As mentioned above and as shown in Fig. 6-60, UGTs can form unusual conjugates including bisglucuronides, diglucuronides, *N*-carbamoyl glucuronides, *N*-glucosides, and other glycoside conjugates. Bisglucuronides (i.e., a glucuronide in which two separate functional groups on the aglycone are glucuronidated) are more common than diglucuronides, and include the bisglucuronides of bilirubin, morphine, octylgallate, diosmetin, phenolphthalein, and hydroxylated PAHs (such as hydroxylated chrysene and B[*a*]P) (Murai et al., 2006). A diglucuronide is a glucuronide in which a single functional group on the aglycone is conjugated twice resulting in two glucuronosyl groups in tandem (Murai et al., 2006). Diglucuronides of the xenobiotics nalmefene and 4-hydroxybiphenyl and of the endogenous steroids androsterone, DHT, 17β-estradiol, estriol, estrone, and testosterone have previously been detected in dogs. Rat liver microsomes do not form diglucuronides of these steroids, whereas monkey liver microsomes form detectable levels of the DHT, testosterone, and 17 β-estradiol diglucuronides, with human liver microsomes forming only the diglucuronide of DHT (see Fig. 6-60) (Murai et al., 2005). In all cases, it is the 2-hydroxyl group of the first glucuronide moiety that is subject to additional glucuronidation. In the case of DHT, only human UGT1A8 (an intestinal UGT) has been found to produce the diglucuronide from DHT itself, although UGT1A4, 2B15, and 2B17 can produce the monoglucuronide, and UGT1A1 and 1A9 can produce the diglucuronide when the monoglucuronide is the substrate (Murai et al., 2006). Human intestinal microsomes form the diglucuronide more efficiently than human liver microsomes, reflecting the fact that UGT1A8, an extrahepatic UGT, is the predominant enzyme involved in the diglucuronidation of DHT.

Although human UGTs typically are highly selective in the use of UDPGA as a sugar donor, they can accommodate the use of other sugar donors such as UDP-glucose, UDP-galactose, and UDP-xylose in an aglycone-dependent manner, as mentioned previously (Tang and Ma, 2005). For instance, recombinant human UGT1A1 can utilize UDPGA, UDP-xylose, or UDP-glucose to form glycosides, but only with bilirubin (Tang and Ma, 2005). Recombinant human UGT2B7 can glycosidate Compound A [(+)-(5*S*,6*R*,7*R*)-2-isopropylamino-7-[4-methoxy-2-((2*R*)-3-methoxy-2-methylpropyl)-5-(3,4-methylenedioxyphenyl)cyclopenteno[1,2-*b*] pyridine 6-carboxylic acid], an endothelin ET_A receptor antagonist, with UDPGA, UDP-glucose, and UDP-galactose, but can glycosidate diclofenac with only UDPGA (Tang and Ma, 2005). In the case of AS-3201, an aldose reductase inhibitor, it was found that UGT2B4, 2B7, and especially 2B15 all *preferentially* utilize UDP-glucose over UDPGA (Toide et al., 2004). Several other compounds have been found to be glucosidated in mammals, including 5-aminosalicylic acid, bromfenac, pranoprofen, pantothenic acid, hyodeoxycholic acid, mycophenolic acid, sulfadimidine, sulfamerazine, sulfamethoxazole, and various barbiturates (e.g., phenobarbital and amobarbital) (Tang and Carro-Ciampi, 1980; Nakano et al., 1986; Arima, 1990; Kirkman et al., 1998; Toide et al., 2004; Picard et al., 2005). In the case of the carboxyl-containing amine, bromfenac, the aglycone was observed in rat bile after base hydrolysis, and it was concluded that it was formed by hydrolysis of an acyl glucuronide (Kirkman et al., 1998). In later studies to characterize the stability of the putative acyl glucuronide, an *N*-glucoside was detected (Kirkman et al., 1998). 5-Aminosalicylic acid is structurally similar to bromfenac in that both NSAIDs contain a primary amine near the carboxyl group, and both are converted to *N*-glucosides (Kirkman et al., 1998). In the human metabolism of barbiturates, *N*-glucosides are the major metabolites found in urine, and glucuronides have not been detected. Accordingly, it was theorized that enzymes other than UGTs may be involved in the conjugation of barbiturates in humans (Toide et al., 2004). This theory is interesting because liver homogenates from cats, which lack UGT activity, can *N*-glucosidate amobarbital (however, it should be noted that glucose conjugates can sometimes form nonenzymatically) (Carro-Ciampi et al., 1985). However, Toide et al. (2004) demonstrated that the *N*-glucosidation of amobarbital in human liver microsomes correlates highly with the *N*-glucosidation of AS-3201, but not its *N*-glucuronidation, indicating that UGT2B15 is probably the predominant human UGT responsible for the glucosidation of amobarbital.

In general, in vivo hepatic clearance is often estimated from kinetic parameters (K_m and V_{max}) determined in vitro with human hepatocytes, liver microsomes, or S9 fraction. The process is commonly used for in vitro–in vivo extrapolation (IVIVE). However, for drugs that are primarily eliminated by glucuronidation, these in vitro studies conducted with liver microsomes and, to a lesser extent, hepatocytes consistently underpredict UGT-mediated clearance in vivo (Miners et al., 2010). There are several intrinsic factors that influence the clearance of glucuronidated compounds in vitro, such as (1) the permeability of the microsomal membranes to allow access of both the aglycone substrate and cofactor UDPGA, (2) the influence of long-chain unsaturated fatty acids released in microsomal incubations, and (3) the homodimerization and heterodimerization of UGT proteins in the endoplasmic reticulum membrane. Additionally, the kinetic properties of UGTs vary in vitro with changes in the incubation conditions (extrinsic factors), such as the concentration of cofactor, membrane composition, partitioning into microsomes, type of buffer, ionic strength, pH, organic solvents (used for the addition of substrates), β-glucuronidase activity, and the stability of the glucuronide in the incubation buffer (Miners et al., 2010). Many of these extrinsic factors are minimized with appropriate experimental conditions. For instance, cofactor availability is overcome with saturating concentrations of UDPGA, typically 2 to 5 mM. However, Fujiwara et al. (2008) reported that UDP, the by-product of glucuronidation reactions, is a competitive inhibitor that blocks binding of UDGPA. Therefore, for in vitro experiments, the concentrations of cofactor must be maintained at very high levels (up to 20 mM UDPGA) to overcome competitive inhibition of the UDPGA binding site by free UDP produced during the incubation, especially for high-turnover UGT substrates such as 1-naphthol. Other common in vitro conditions for microsomal assays include the addition of the pore-forming peptide alamethicin or zwitterionic detergent CHAPS (described below), the addition of saccharic acid-1,4-lactone to inhibit β-glucuronidase, and the acidification (pH 5 to 6.8) of the organic solvent used to stop reactions when acyl glucuronide formation is expected (Miners et al., 2010).

In vitro intrinsic metabolic clearance (CL_{int}) values (measured as V_{max}/K_m) for zidovudine (AZT) glucuronidation in human liver microsomes were shown to vary sixfold depending on incubation conditions, but even under conditions that produced the greatest CL_{int}, the in vivo clearance rate was underpredicted by three- to fourfold (Miners et al., 2006). This in vitro underprediction of the in vivo rate of clearance of drugs that are glucuronidated is typical when human liver microsomes are used to assess CL_{int}, and is likely due to a number of factors including the presence or absence of albumin, the effects of long-chain unsaturated fatty acids, correction for membrane partitioning, atypical in vitro kinetics, active uptake into hepatocytes, and significant extrahepatic expression of various UGTs (Miners et al., 2010). The prediction of the in vivo clearance

of drugs that are glucuronidated by hepatocytes is generally more accurate than predictions made with microsomes, but underprediction is still the common outcome. Zidovudine is an exception to this rule because its in vivo clearance is accurately predicted from in vitro studies with hepatocytes (Miners et al., 2006). The use of either microsomes or recombinant UGT2B7 also underpredicts the in vivo magnitude of the *inhibitory* interaction between fluconazole and zidovudine by 5- to 10-fold (Miners et al., 2006). However, when 2% bovine serum albumin (BSA) is added to either test system, there is a decrease in the K_i value of 85% which results in a much improved prediction of the in vivo interaction (Miners et al., 2006). The effect of BSA is due to the sequestration of inhibitory fatty acids released from membranes during the incubation. The BSA or "albumin" effect is also observed with fatty-acid-free human serum albumin (HSA-FAF) added to incubations. The K_m values of reactions catalyzed by UGT1A9 and UGT2B7 are markedly influenced by the presence of free fatty acids released from microsomal membranes (notably arachidonic, linoleic, and oleic acids) and albumin serves as a fatty acid scavenger. Similarly, the addition of intestinal fatty acid–binding protein (IFABP) to microsomal incubations decreased the K_m values for zidovudine glucuronidation, a UGT2B7 substrate (Rowland et al., 2009). Unsaturated long-chain fatty acids are potent competitive inhibitors of some, but not all, UGT enzymes and can lead to overestimation of K_m values and, therefore, underprediction of CL_{int}. Furthermore, the effect of fatty acids varies depending on the membrane composition of the enzyme source (recombinant vs. microsomes vs. hepatocytes) inasmuch as kinetic constants for a specific reaction may vary based on the test system. Unlike UGT1A9 and UGT2B7, fatty acids have little to no effect on reactions catalyzed by UGT1A1, 1A4, and 1A6 (Miners et al., 2010).

The glucuronidation of xenobiotics by liver microsomes in vitro displays a property known as latency inasmuch as it can be stimulated by detergents (e.g., CHAPS and Brij-58) and the pore-forming peptide alamethicin, which disrupt the lipid bilayer of the endoplasmic reticulum and allow UGTs free access to UDPGA. High concentrations of detergent, especially nonionic detergents such as Brij, can inhibit certain UGTs, presumably by disrupting their interaction with phospholipids, which are important for catalytic activity (Fisher et al., 2000). Treatment of microsomes with detergents also virtually eliminates CYP activity; hence, detergents cannot be used to study the possible coupling of oxidation reactions catalyzed by CYP with conjugation reactions catalyzed by UGT. This is not a limitation of alamethicin which does not inhibit CYP. Furthermore, in contrast to certain detergents, alamethicin increases V_{max} without affecting K_m. From a review of the literature, Miners et al. (2006) reported that alamethicin and nonionic detergents such as Brij-58 generally result in the highest UGT activity and that alamethicin is the preferred activator because the effects of detergents are not reproducible between substrates. However, in incubations designed strictly to measure UGT activity (and not both UGT and CYP activity), the zwitterionic detergent, CHAPS, can activate certain UGT activities to a comparable or even greater extent than alamethicin.

The kinetic properties of UGTs are possibly influenced by the formation of homodimers and heterodimers among UGT enzymes and by the formation of heterodimers with other microsomal enzymes such as various CYP enzymes, POR, or epoxide hydrolase (Ishii et al., 2010). For instance, it has been demonstrated that the ratio of morphine-3-glucuronide to morphine-6-glucuronide formed by UGT2B7 is altered by the presence of CYP3A4. The K_m of UGT2B7-catalyzed formation of morphine-3-glucuronide was increased 9.8-fold (0.38 to 3.7 μM) when coexpressed with CYP3A4 (Takeda et al., 2005; Ishii et al., 2010). Fremont et al. (2005) reported that UGT1A1, 1A6, and 2B7 coimmunoprecipitated with CYP3A4 in solubilized human liver microsomes. If there are functional consequences to the associations between different UGT enzymes and/or the association between UGT and CYP enzymes, then such associations would have implications for studies with recombinant UGT enzymes, which are invariably expressed individually.

Advances in mass spectrometry have enabled the quantification of UGT proteins in samples of human liver, intestinal and kidney microsomes, recombinant UGT enzymes, and cultured hepatocytes (see Table 6-22), which permits extrapolation of rates of glucuronidation from these in vitro systems to the in vivo situation as is done with CYP enzymes (through the application of relative activity factors [RAF] or intersystem extrapolation factors [ISEF]) (Harbourt et al., 2012; Ohtsuki et al., 2012; Fallon et al., 2013; Achour et al., 2014; Sato et al., 2014). The role of heteromeric or homomeric expression of UGTs in vivo is largely undefined. Several publications have investigated the coexpression of UGT enzymes in vitro with cell lines overexpressing various UGTs with mixed results: enhancement of some activities and impairment of others (Ishii et al., 2010). Finally, posttranslational modifications to UGTs that occur in vivo in humans (e.g., phosphorylation and *N*-glycosylation) may not occur in the cell expression system chosen to produce the recombinant UGTs (i.e., bacterial systems), which can impact activity in a substrate-dependent manner (Miners et al., 2006). All of these findings suggest that the use of recombinant human UGT enzymes may not provide accurate indications of the extent to which a given UGT can glucuronidate a given substrate.

Glucuronidation can be impaired by cofactor availability, polymorphisms, drug–drug interactions, or the effects of endogenous or dietary compounds, any of which can result in toxicities due to decreased elimination of certain compounds (e.g., bilirubin). Cofactor availability can limit the rate of glucuronidation of drugs that are administered in high doses and are conjugated extensively, such as aspirin and acetaminophen. In experimental animals, the glucuronidation of xenobiotics can be impaired in vivo by factors that reduce or deplete UDPGA levels, such as diethyl ether, borneol, and galactosamine. The lowering of UDPGA levels by fasting, such as might occur during a severe toothache or oral cancer, is thought to predispose individuals to the hepatotoxic effects of acetaminophen, although even then hepatotoxicity only occurs with higher-than-recommended doses of this analgesic (Whitcomb and Block, 1994; Rumack, 2004).

Drug–drug interactions that are at least partly due to inhibition of UGTs have been reported; however, the drug–drug interactions caused by UGT inhibition rarely cause increases in the plasma AUC of the victim drug more than twofold (Williams et al., 2004). Valproic acid, which inhibits the clearance of lamotrigine, lorazepam, and ziduvodine), and probenecid, which inhibits the clearance of acetaminophen, clofibrate, lorazepam, and ziduvodine, are the two drugs most commonly associated with clinically relevant inhibition of UGT activity (Rowland et al., 2013). Particular attention is paid to investigational drugs that inhibit UGT1A1, the major bilirubin-conjugating enzyme. Administration of the protease inhibitors atazanavir and indinavir to HIV patients can lead to reversible hyperbilirubinemia due to inhibition of UGT1A1 (Zhang et al., 2005). The potential for atazanavir to cause hyperbilirubinemia is increased in individuals with genetic polymorphisms that decrease the activity of UGT1A1, namely UGT1A1*28 and UGT1A1*37 (discussed later in this section), and already have elevated levels of

bilirubin (Gammal et al., 2016). Clinically relevant drug–drug interactions due to induction of UGT enzymes have also been observed. Rifampin coadministration increases mycophenolic acid clearance by 30%, and increases the AUC of its acyl glucuronide (formed by UGT2B7) and its 7-*O*-glucuronide (formed by various UGT1 enzymes) by more than 100% and 20%, respectively (Naesens et al., 2006). Similarly, rifampin coadministration in humans causes a decrease in the systemic AUC of some UGT substrates, including raltagravir (UGT1A1; decreases AUC by 40%) and zidovudine (UGT2B7; decreases AUC 30% to 50%) (Gallicano et al., 1999; Wenning et al., 2009). Coadministration of other drugs, such as the enzyme-inducing antiepileptics (e.g., phenobarbital), and certain physiological conditions (e.g., increased levels of estrogens during pregnancy) can cause an increase of hepatic UGT enzymes and, therefore, the clearance of some UGT substrates. The CAR agonists phenobarbital and the Chinese herbal Yin Zhi Huang (active ingredient scoparone [6,7-dimethylesculetin]) have been used for the treatment of neonatal jaundice due to their ability to induce the UGT1A1-dependent glucuronidation of bilirubin (a treatment no longer practiced with phenobarbital). In general, the magnitude of drug–drug interactions due to UGT enzyme induction is less than those reported for CYP-mediated induction. Although inhibition and induction of UGT enzymes are associated with modest changes (usually less than twofold) in the clearance of drugs that undergo glucuronidation, certain genetic polymorphisms have a profound impact (more than 100-fold) on systemic exposure to certain investigational drugs that are substrates for UGT2B10 or UGT2B17, as discussed later in this section.

Human UGT1A6 glucuronidates acetaminophen. This reaction is enhanced by cigarette smoking and dietary cabbage and Brussels sprouts, which suggests that human UGT1A6 is inducible by PAHs and derivatives of indole 3-carbinol, but not to the extent observed in rats (Bock et al., 1994). Ligands for AhR, such as those present in cigarette smoke, induce CYP1A2, which would be expected to enhance the hepatotoxicity of acetaminophen. Increased acetaminophen glucuronidation may explain why cigarette smoking does not enhance the hepatotoxicity of acetaminophen. Conversely, decreased glucuronidation may explain why some individuals with Gilbert syndrome are predisposed to the hepatotoxic effects of acetaminophen (de Morais et al., 1992). Low rates of glucuronidation predispose newborns to jaundice and to the toxic effects of chloramphenicol; the latter was once used prophylactically to prevent opportunistic infections in newborns until it was found to cause severe cyanosis and even death (gray baby syndrome).

Some glucuronide conjugates have been found to act as substrates for further biotransformation by oxidation or even by further conjugation. For instance, in male WAG/Rij rats, estradiol 17β-glucuronide can be sulfonated by one or more sulfotransferases (SULTs) to estradiol 3-sulfate-17 β-glucuronide (Sun et al., 2006). In addition, the acyl glucuronide of 4-hydroxydiclofenac can be formed either by a combination of 4′-hydroxylation followed by acyl glucuronidation or by a combination of acyl glucuronidation followed by 4′-hydroxylation. In the former case, the 4′-hydroxylation of diclofenac is catalyzed by CYP2C9, whereas in the latter case the 4′-hydroxylation of diclofenac acyl glucuronide is catalyzed by CYP2C8 (Kumar et al., 2002). Glucuronidation converts several other CYP2C9 substrates into CYP2C8 substrates or inhibitors. For instance, CYP2C8 catalyzes the oxidation of several glucuronides, the aglycones of which are CYP2C9 substrates, including estradiol 17β-glucuronide and the acyl glucuronides of naproxen, the PPARα/agonist MRL-C, gemfibrozil (Delaforge et al., 2005; Kochansky et al., 2005; Ogilvie et al., 2006). Desloratadine undergoes 3-hydroxylation by CYP2C8 (to form 3-hydroxydesloaratdine, a human-predominant metabolite) but only after desloratadine is *N*-glucuronidated by UGT2B10, as shown in Fig. 6-54 (see the section "CYP2C8"). Despite its instability, desloratadine *N*-glucuronide is an obligatory intermediate in the conversion of desloratadine to 3-hydroxydesloratadine by CYP2C8 (Kazmi et al., 2015a, 2015b).In the case of gemfibrozil and clopidogrel (following ester hydrolysis to its acidic metabolite), glucuronidation produces metabolites, namely acyl glucuronides, that cause irreversible (metabolism-dependent) inhibition of CYP2C8, which is the mechanism by which gemfibrozil and clopidogrel increase systemic exposure to cerivastatin leading to increased myotoxicity of this statin (see the section "CYP2C8") (Ogilvie et al., 2006; Tornio et al., 2014). Similar to its inhibition of CYP2C8, gemfibrozil and its glucuronide are inhibitors (and substrates) of the organic anion transporter OATP1B1 on the sinusoidal membrane of hepatocytes. Inhibition of OATP1B1 by gemfibrozil and gemfibrozil glucuronide accounts, at least in part, for the pharmacokinetic drug–drug interaction between gemfibrozil and several statin drugs whose systemic clearance is predominately through OATP-mediated hepatic uptake, namely, pravastatin and rosuvastatin (Tornio et al., 2008). Although inactivation of CYP2C8 by gemfibrozil glucuronide and clopidogrel glucuronide are the only known examples of CYP inactivation by the glucuronide metabolites of clinically used drugs, Kazmi et al. (2010) identified a carbamoyl-glucuronide of an investigational drug that caused irreversible (metabolism-dependent) inhibition of CYP2C8 in vitro, the clinical significance of which is unknown.

Glucuronidation is important for the conversion of atorvastatin acid to its pharmacologically inactive lactone form at physiological pH; however, the formation of atorvastatin lactone is also associated with dose-limiting toxicities (Riedmaier et al., 2011). Atorvastatin (Lipitor) is administered as a free acid but is found in systemic circulation at levels similar to its pharmacologically inactive lactone based on plasma AUC. The major cause of adverse events associated with atorvastatin therapy is myopathy (skeletal muscle toxicity) which, in severe cases, can result in rhabdomyolysis and fatal kidney failure. In vitro studies with the acid and lactone forms of atorvastatin in primary skeletal muscle cells established that the lactone form is 14 times more potent than the acid form at inducing cell death. Both atorvastatin acid and lactone can undergo oxidative metabolism by CYP3A4 and CYP3A5 to form *ortho*- and *para*-hydroxylated metabolites. Atorvastatin acid also undergoes glucuronidation to form atorvastatin acyl glucuronide. The conversion of atorvastatin acid to its pharmacologically inactive lactone occurs nonenzymatically at low pH (e.g., intestine) or enzymatically at physiological pH (7.4); the latter is dependent on formation of the acyl glucuronide (Riedmaier et al., 2011). The glucuronide moiety is a good leaving group and is lost during the lactonization reaction. Based on in vitro and in vivo studies, Riedmaier et al. (2010) identified UGT1A3 as the enzyme largely responsible for the lactonization of atorvastatin and further demonstrated that the paraoxonases PON1 and PON3 are responsible for the hydrolysis of atorvastatin lactone back to the acid form. Taken together, UGT1A3, PON1, and PON3 are important determinants of the atorvastatin acid–lactone ratio in vivo and, hence, the potential for atorvastatin myopathy and rhabdomyolysis.

Kumar et al. (2002) demonstrated that failure to take into account the formation of the acyl glucuronide of 4′-hydroxydiclofenac leads to an underestimation of hepatic clearance of diclofenac. It may also be that oxidation of glucuronide metabolites can lead to toxicity. A case report described the formation of an IgM antibody that bound erythrocytes, but only in the presence of

the 4-hydroxydiclofenac acyl glucuronide in a patient who developed hemolysis (hemolytic anemia) during diclofenac treatment (Shipkova et al., 2003). A determination of the absolute amount of diclofenac acyl glucuronide formed in vivo relative to the amount of 4-hydroxydiclofenac formed in vivo would be confounded by the rapid hydrolysis of the glucuronide to the aglycone, and it would therefore be likely that detection of 4-hydroxydiclofenac acyl glucuronide would be attributed to oxidative metabolism occurring prior to conjugation. Two reports suggest that direct glucuronidation with subsequent oxidation (by a combination of UGT2B7 and CYP2C8 in humans) may be the major determinants of diclofenac clearance in humans (possibly as high as 75%) and monkeys (more than 90%) (Kumar et al., 2002; Prueksaritanont et al., 2006), as opposed to earlier in vivo data that suggested oxidative metabolism by CYP2C9 alone is the major determinant of clearance (Stierlin and Faigle, 1979; Stierlin et al., 1979). In support of this interpretation, there are no clinical reports that implicate pharmacokinetic interactions between diclofenac and potent CYP2C9 inhibitors or inducers (Prueksaritanont et al., 2006). Taken together, these observations suggest that the CYP-mediated oxidation of glucuronide metabolites has implications not only for the prediction of in vivo drug–drug interactions from in vitro data (i.e., gemfibrozil and clopidogrel) but also for the prediction of in vivo clearance (i.e., diclofenac), and possibly also toxicity, as in the case of immune-mediated toxicity of diclofenac.

In humans, Crigler–Najjar syndrome (types I and II) and Gilbert disease are congenital defects in bilirubin conjugation. The diseases have historically been differentiated largely on the basis of the severity of symptoms and total plasma concentrations of bilirubin (e.g., Crigler–Najjar type I: 310 to 855 μM, Crigler–Najjar type II: 100 to 430 μM, and Gilbert disease: 20 to 100 μM). The major bilirubin-conjugating enzyme in humans is UGT1A1. Genetic polymorphisms in exons 2 to 5 (which affect all enzymes encoded by the UGT1A locus), in exon 1 (which affect only UGT1A1), in the promoter regions, and in introns 1 and 3 have been identified in patients with Crigler–Najjar syndrome or Gilbert disease. More than 60 genetic polymorphisms are associated with these diseases. A current list of all UGT polymorphisms and phenotypes (when known) can be found at https://www.pharmacogenomics.pha.ulaval.ca/ugt-alleles-nomenclature/. Some polymorphisms cause the introduction of a premature stop codon in one of the UGT1A common exons 2 to 5 (which causes a loss of all UGT1A enzymes, analogous to the Gunn rat) and are associated with type I Crigler–Najjar syndrome, a severe form of the disease characterized by a complete loss of bilirubin-conjugating activity and marked hyperbilirubinemia. Type I Crigler–Najjar syndrome is also associated with various frameshifts and deletions in exons 1 to 5, and in at least three cases with changes in introns 1 and 3 that affect splice donor or acceptor sites. Other polymorphisms are associated with the less severe type II Crigler–Najjar syndrome (i.e., UGT1A1*7–9, 12, 26, 30, 33-38, 42, 48, 51, 52, 59, and 64). Individuals with Gilbert disease have an occasionally transient, and generally mild, hyperbilirubinemia that is often caused by the addition of one "TA" segment in the TATA promoter region (i.e., UGT1A1*28: $A(TA)_6$**TAA** → **A(TA)**$_7$TAA). There is some overlap between Crigler–Najjar type II and Gilbert disease, not only in terms of the plasma concentrations of bilirubin but also in the type of polymorphism that underlies the disease. In addition to the *28 allele, the *6, *27, *29, *60, and *62 alleles are associated with Gilbert disease, and some of these polymorphisms affect coding regions of the UGT1A1 gene. In addition, the UGT1A1*37 allele produces a $A(TA)_8$TAA promoter defect that results in Crigler–Najjar type II disease. A Korean individual heterozygous for three UGT1A1 alleles associated with Gilbert disease (i.e., likely *6, *28, and *60) was found to have total bilirubin concentrations as high as 193 μM (Seo et al., 2007), which is a concentration typically associated with Crigler–Najjar type II disease. Crigler–Najjar type II and Gilbert diseases (in contrast to Crigler–Najjar type I disease) typically respond to some extent to phenobarbital treatment, which stimulates bilirubin conjugation by inducing UGT1A1. Type I Crigler–Najjar syndrome is also associated with impaired glucuronidation of propofol, ethinylestradiol, and various phenolic substrates for UGT1A enzymes.

Genetic variants that impair UGT1A1 activity, notably the *6, *28, and *37 allelic variants, are clinically important due to their impact on the toxicity of the topoisomerase I inhibitor irinotecan, which is used primarily to treat colorectal cancer. The disposition of irinotecan is complex. Irinotecan (a prodrug) is administered intravenously with hydrolysis to the active metabolite, SN-38, occurring mainly by tissue carboxylesterases, namely, CES2, and hydrolytic enzymes in plasma. The active metabolite SN-38 is subsequently glucuronidated in the liver primarily by UGT1A1 after which the glucuronide conjugate is excreted into bile. Other UGT enzymes that contribute to glucuronidation, at least in part, include hepatic UGT1A6 and UGT1A9 and intestinal UGT1A7 and UGT1A10 (Nagar and Blanchard, 2006; Wallace et al., 2010). The UGT1A1*28 variant has now been referenced in the Camptosar® prescribing information, which notes that patients with reduced UGT1A1 activity have a higher exposure to SN-38 (which is 50 to 100 times more toxic than the glucuronide), and that the dose of irinotecan should be adjusted downward accordingly (Nagar and Blanchard, 2006). The toxicity of SN-38 primarily manifests as severe diarrhea and myelosuppression (in the form of leucopenia, severe thrombocytopenia, severe anemia, or grade 3 to 4 neutropenia) (Nagar and Blanchard, 2006). Several studies have demonstrated grade 3 to 4 neutropenia and/or grade 3 to 4 diarrhea upon irinotecan administration in patients with at least one UGT1A1*28 or UGT1A*27 allele, and one study implicated *high*-activity variants of UGT1A7 and UGT1A9 with diarrhea (Nagar and Blanchard, 2006).

Inhibition of bacterial β-glucuronidase is a potential pharmacological approach to overcome the severe diarrhea associated with irinotecan (CPT-11) chemotherapy (Wallace et al., 2010). Hydrolysis of SN-38-*O*-glucuronide (SN-38G) by bacterial β-glucuronidase in the gastrointestinal tract releases the pharmacologically active SN-38 into the intestinal lumen where it can be reabsorbed and cause dose-limiting diarrhea. The β-glucuronidase enzyme responsible for hydrolysis of SN-38G in the gut is found in the symbiotic microbiota. Wallace et al. (2010) identified four compounds that potently (K_i values in the nanomolar range) and specifically inhibit *Escherichia coli* β-glucuronidase, but not human β-glucuronidase activity, by targeting a 17-residue loop in the bacterial enzyme that is not present in mammalian forms (Wallace et al., 2010). Inhibition of *E. coli*–specific β-glucuronidase protected mice from the GI toxicity of irinotecan (Wallace et al., 2010). Taken together, these results suggest that β-glucuronidase may be a potential pharmacological target to limit pharmacokinetic or toxicological concerns associated with hydrolysis of glucuronides in the gastrointestinal tract, which may lead to reabsorption of, and prolonged exposure to, the aglycone.

Genetic polymorphisms have been identified in UGT2B4, 2B7, 2B10, 2B15, 2B17, and 2B28. Until recently, these were thought to have a modest impact on systemic exposure to drugs (Rowland et al., 2013; Mazerska et al., 2016). However, that view changed with reports of dramatic changes (more than 25-fold

increase) in systemic exposure to two investigational drugs that were associated with genetic polymorphisms in either UGT2B10 or UGT2B17. A genetic polymorphism in UGT2B10 (caused by a splice site mutation that prevents synthesis of functional enzyme) was identified as the cause of a 136-fold increase in systemic exposure to RO5263397, a drug candidate under investigation for the treatment of schizophrenia, in an individual enrolled in a clinical trial (Fowler et al., 2015). Further clinical studies identified two additional PMs, all of African descent and all with the same splice variant of UGT2B10. Interestingly, in vitro reaction phenotyping studies with a panel of recombinant human UGT enzymes pointed to UGT1A4 as the enzyme primarily responsible for the *N*-glucuronidation of RO5263397, but this study did not include UGT2B10, which was subsequently identified as a high-affinity enzyme capable of catalyzing the *N*-glucuronidation of RO5263397 (Fowler et al., 2015). The UGT2B10 splice variant (rs2942857 variant C allele) was found in Africans with a frequency of 45%, compared with 7% in Native Americans, 8% in Asians, and 0% in Caucasians. As discussed in the section "CYP2C8," this variant is a likely cause of (or at least a contributor to) the PM phenotype for desloratadine 3-hydoxylation, a reaction that requires *N*-glucuronidation of desloratadine by UGT2B10 (see Fig. 6-54) and is impaired mainly in individuals of African descent, although genetic polymorphisms that impair CYP2C8 could give rise to the same PM phenotype.

The second example of a genetic polymorphism of UGT greatly impacting systemic exposure to an investigational drug involves MK-7246, a carboxylic acid–containing compound under development for the treatment of respiratory diseases based on its ability to antagonize the chemoattractant receptor on T helper type 2 cells (a CRTH2 antagonist). Clearance of MK-7246 is mainly due to acyl glucuronidation by UGT2B17. In individuals with no UGT2B17 activity (UGT2B17*2/*2 carriers), the plasma AUC and C_{max} of MK-7246 was 25- and 82-fold greater than in individuals harboring the wild-type enzyme (UGT2B17*/*1) (Wang et al., 2012). UGT2B17 (as well as UGT2B15) also plays an important role in the glucuronidation of dihydrotestosterone, testosterone, and androsterone, which terminates androgen signaling in prostate and other androgen target cells. Genetic polymorphisms that decrease UGT2B17 activity or expression, like the *2 allele, have attracted attention for their impact on circulating androgen levels, such as sports doping and some instances of an increased risk of prostate cancer, among others (Guillemette et al., 2010; Gauthier-Landry et al., 2015).

Oxazepam is glucuronidated by UGT2B15, which preferentially glucuronidates *S*-oxazepam over its *R*-enantiomer. Ten percent of the population appear to be poor glucuronidators of *S*-oxazepam, and one study has implicated the low-activity UGT2B15*2 allele as a possible determinant of such variation (Nagar and Remmel, 2006). Such polymorphisms also appear to be the underlying cause of alterations in hyodeoxycholate glucuronidation in gastric mucosa (Tukey and Strassburg, 2000).

In some cases, glucuronidation represents an important event in the toxicity of xenobiotics. For example, the aromatic amines that cause bladder cancer (such as benzidine, 2-aminonaphthalene, and 4-aminobiphenyl) undergo *N*-hydroxylation in the liver (*aryl*-NH_2 → *aryl*-NHOH) followed by *N*-glucuronidation (not *O*-glucuronidation) of the resultant hydroxylamine. Direct *N*-glucuronidation (prior to *N*-hydroxylation) also occurs, and is a competing pathway of hepatic metabolism. In the case of 4-aminobiphenyl, the competing pathways of ring hydroxylation and *O*-esterification (i.e., *O*-glucuronidation, *O*-sulfonation, or *O*-acetylation) are detoxication pathways, whereas *N*-esterification catalyzed by UGTs, SULTs, or NATs represent activating pathways (see the section "Acetylation") (Cohen et al., 2006). Benzidine and 2-aminonaphthalene are particularly tumorigenic. The risk of bladder cancer may increase by up to 100-fold in workers exposed to these substances in the course of their occupation in various manufacturing processes (Al-Zoughool et al., 2006). The *N*-glucuronides of such carcinogens, which accumulate in the urine of the bladder, are unstable in acidic pH and thus are hydrolyzed to the corresponding unstable, tumorigenic hydroxylamines, as shown in Fig. 6-62. Under acidic conditions, hydroxylamines can produce highly electrophilic aromatic nitrenium ions (*aryl*-NHOH + H^+ → *aryl*-N^+ + H_2O) that can bind to DNA and other macromolecules, or they can be converted to reactive acetoxy metabolites directly in the bladder epithelium by NAT-mediated *O*-acetylation (*aryl*-NH–O–CO–CH_3), which also leads to the formation of aromatic nitrenium ions (Al-Zoughool et al., 2006). Because *N*-glucuronidation of aromatic amines can also occur directly without prior oxidation, this reaction competes with oxidation, and therefore a decrease in UGT activity in the liver would favor *N*-hydroxylation, with subsequent *O*-acetylation by NAT and spontaneous formation of aromatic nitrenium ions in the liver, rather than the bladder. In contrast, decreased acetylation with normal UGT activity would lead to a greater accumulation of *N*-glucuronides (of the parent aromatic amine and its hydroxylamine) in the bladder with increased bladder tumor formation. Concordant with this scenario, benzidine induces predominantly liver tumors in rats (fast acetylators) but bladder cancer in dogs (poor acetylators) (Al-Zoughool et al., 2006). In humans, there are sex differences in aromatic amine carcinogenicity. Irrespective of ethnicity or race, men are 2.5 to 5 times more likely to develop bladder cancer than women in general. In particular male smokers, hairdressers, and dye and textile workers who are exposed to aromatic amines have several times increased risk relative to their female counterparts. Male mice, which *N*-glucuronidate 4-aminobiphenyl faster than females, were found during the treatment with this carcinogen to have a 2.2-fold higher rate of DNA-adduct formation, and increased rates of bladder tumor formation relative to females, and female mice were found to have tumors only in the liver (Al-Zoughool et al., 2006). In mice, coadministration of 4-aminobiphenyl with hecogenin, which in humans has been found to inhibit hepatic UGT1A4 (Uchaipichat et al., 2006), was found to increase DNA-adduct formation in a statistically significant manner in the livers of male mice, and to slightly decrease adduct formation in the bladders of both male and female mice (Al-Zoughool et al., 2006). The available literature regarding sex differences in human UGT activity is conflicting. Glucuronidation of temazepam, oxazepam, propranolol, and salicylic acid was 20% to 60% higher in men than in women (Al-Zoughool et al., 2006), whereas 4-methyumbelliferone glucuronidation in cryopreserved human hepatocytes was found to be an average of 40% higher in female samples ($n = 33$) than in male samples ($n = 31$). The carcinogenicity of aromatic amines is multifactorial, and involves not only hepatic *N*-glucuronidation but also hepatic oxidation, hepatic and bladder acetylation, and possibly peroxidation of *N*-hydroxy-*N*-acetyl aromatic amines in the bladder (Al-Zoughool et al., 2006). Therefore, sex differences in UGT activity alone may not fully explain the sex differences observed in the carcinogenicity of aromatic amines. A similar mechanism may be involved in colon tumor formation by aromatic amines, although in this case hydrolysis of the *N*-glucuronide is probably catalyzed by β-glucuronidase in intestinal microbiota. Aromatic amides (such as phenacetin) can also be *N*-hydroxylated by CYP (and peroxidases) to form hydroxamic acids: *aryl*-N(OH)–$COCH_3$. Under acidic conditions (such as in urine), these can lose water to form reactive nitrenium ions that are thought to contribute to the

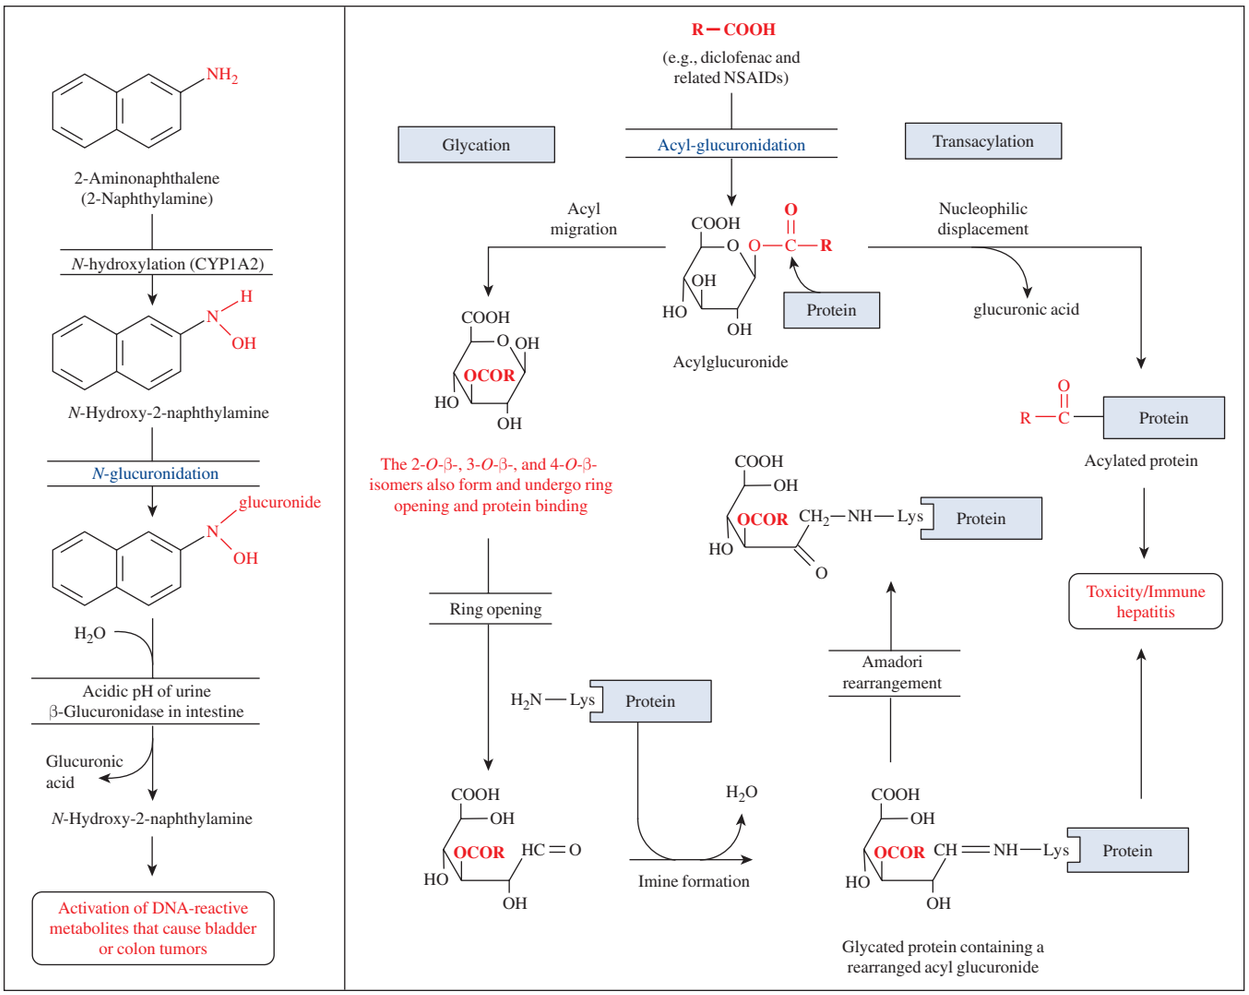

Figure 6-62. *Role of glucuronidation in the activation of xenobiotics to toxic metabolites.*

renal toxicity of phenacetin. The N–OH group can also be conjugated, which introduces a good leaving group. This represents a second pathway to nitrenium ion formation (Testa and Krämer, 2008, 2010).

Steroid hormones glucuronidated on the D-ring (but not the A-ring) cause cholestasis. For instance, 17β-estradiol-glucuronide causes cholestasis in rats by inhibition of MRP2 and BSEP, which are transporters located on the apical membrane of hepatocytes and are important for biliary efflux of endobiotics and xenobiotics, and formation of bile (Huang et al., 2000; Stieger et al., 2000). Induction of UGT activity has been implicated as a nongenotoxic mechanism of thyroid tumor formation in rodents (McClain, 1989; Curran and DeGroot, 1991). Inducers of UGTs cause a decrease in plasma thyroid hormone levels, which triggers a compensatory increase in thyroid stimulating hormone (TSH). During sustained exposure to the enzyme-inducing agent, prolonged stimulation of the thyroid gland by TSH (more than 6 months) results in the development of thyroid follicular cell neoplasia. Glucuronidation followed by biliary excretion is a major pathway of thyroxine (T4) biotransformation in rodents, whereas deiodination is the major pathway (up to 85%) of T4 metabolism in humans. In contrast to the situation in rodents, prolonged stimulation of the thyroid gland by TSH in humans will result in malignant tumors only in exceptional circumstances and possibly only in conjunction with some thyroid abnormality. Therefore, chemicals that cause thyroid tumors in rats or mice by inducing UGT activity are unlikely to cause such tumors in humans. In support of this conclusion, extensive epidemiological data in epileptic patients suggest that phenobarbital and other anticonvulsants do not function as thyroid (or liver) tumor promoters in humans (Parkinson et al., 2006; Elcombe et al., 2014; Lake et al., 2015).

Earlier in this chapter the metabolic activation of drugs to reactive metabolites was discussed on the basis of structural class (acidic vs. neutral/basic) and is illustrated in Fig. 6-63. In particular, acidic drugs (e.g., NSAIDs) can undergo conjugation by UGTs to form acyl glucuronides and/or conjugation with amino acids through the formation of acyl-CoA thioesters catalyzed by mitochondrial acyl-CoA ligases (see the section "Amino Acid Conjugation"). Both conjugation pathways potentially lead to formation of chemically reactive metabolites that have the intrinsic ability to covalently modify proteins by glycation (acyl glucuronides) and/or transacylation (acyl glucuronides and acyl-CoA

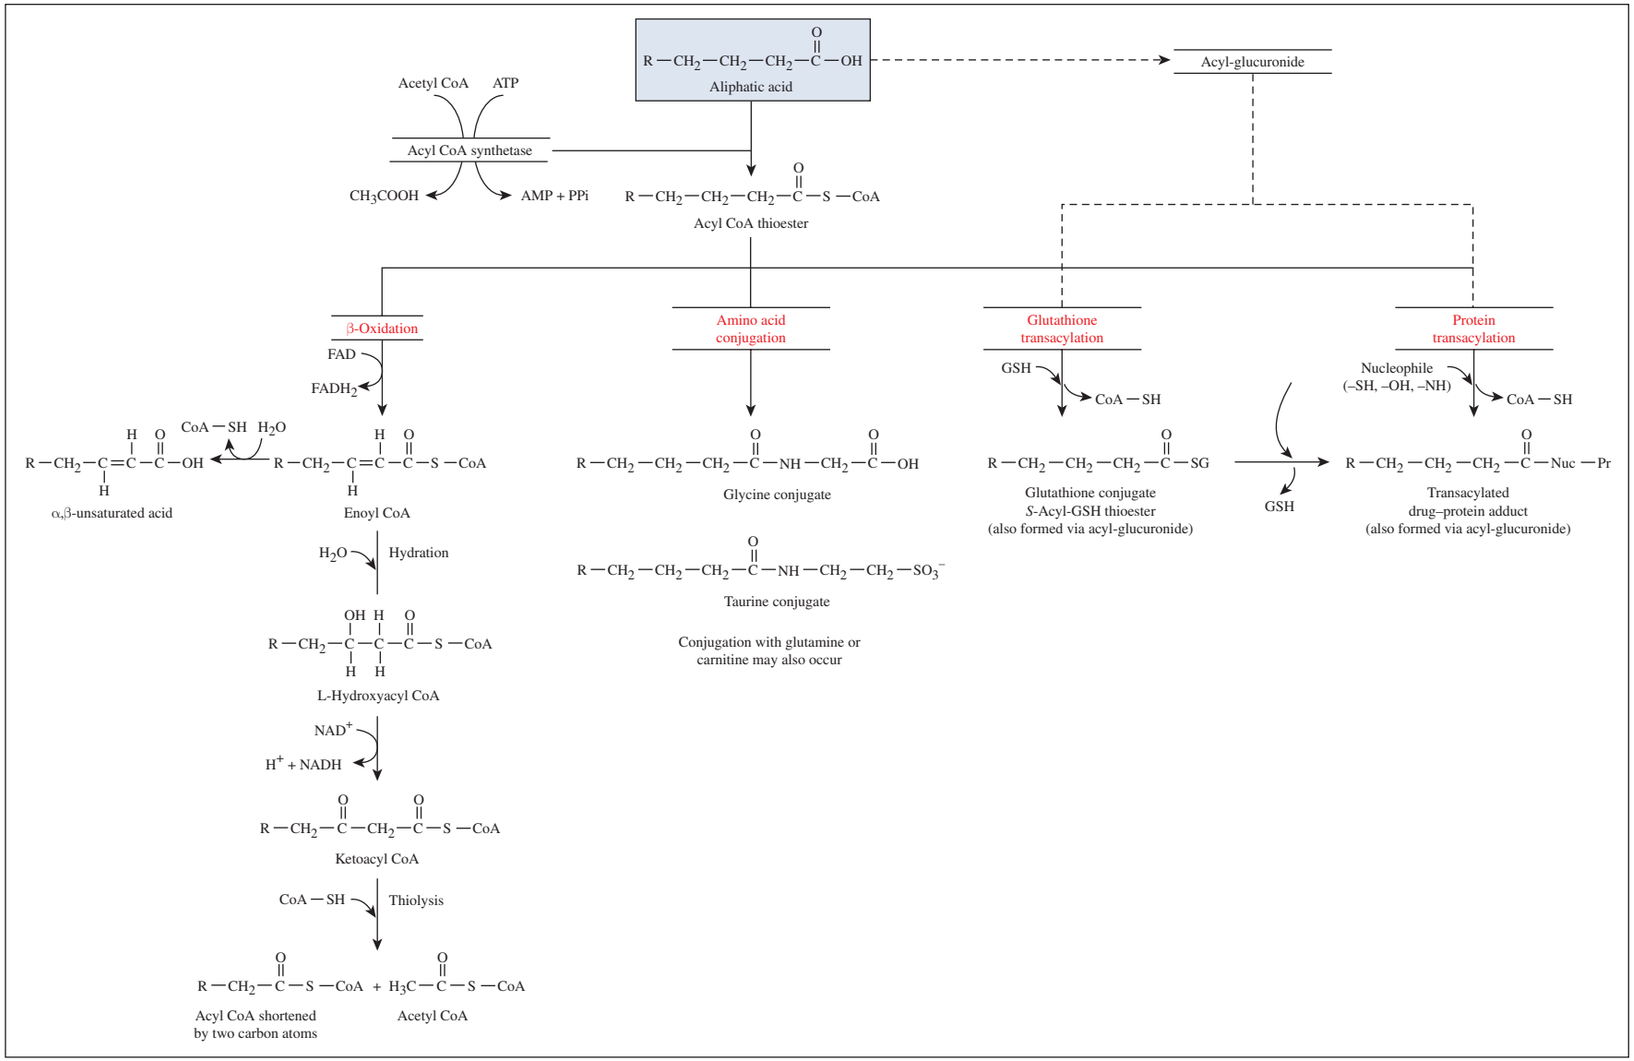

Figure 6-63. *Conversion of carboxylic acid–containing xenobiotics to acyl-CoA thioesters and their subsequent biotransformation by chain shortening by β-oxidation, conjugation with amino acid, and transacylation with glutathione and protein.*

thioesters) (Iwamura et al., 2017; Van Vleet et al., 2017). Reactive acyl glucuronides glycate amine group of lysine residues through Schiff base formation (in which case the glucuronide moiety covalently modifies the protein) and they can also transacylate proteins by nucleophilic displacement reactions (in which case the glucuronic acid moiety serves as the leaving group and is not covalently bound to the protein), as shown in Fig. 6-63 (Regan et al., 2010). Similarly, acyl-CoA thioesters can transacylate proteins at nucleophilic sites (such as lysine, serine, cysteine, and tyrosine residues), in which case the thio-CoA moiety is the leaving group (Grillo, 2011). An important difference between acyl glucuronides and acyl-CoA thioesters is that only the former are transported into bile where they can damage cholangiocytes and other bile duct cells (discussed later in this section). Several drugs, including the NSAIDs benoxaprofen, bromfenac, diclofenac, diflunisal, etodolac, fenoprofen, flurbiprofen, indoprofen, ketoprofen, ketorolac, loxoprofen, sulindac, suprofen (very similar to the diuretic, tienilic acid), tiaprofenic acid, tolmetin, and zomepirac, contain a carboxylic acid moiety that can be glucuronidated to form a reactive acyl glucuronide that can form covalent adducts with proteins. Acyl glucuronides vary widely in their reactivity, from the highly reactive zomepirac and tolmetin acyl glucuronides to the less reactive acyl glucuronides of ibuprofen and salicylic acid (Shipkova et al., 2003). A relationship between the reactivity of acyl glucuronides and the substitution near the carboxylic acid has been found. In general, α-unsubstituted acetic acid derivatives such as zomepirac, tolmetin, and diclofenac exhibit the highest degree of covalent binding, whereas mono-α-substituted acetic acids such as fenoprofen show intermediate levels, and fully substituted α-acetic acids such as furosemide, ketoprofen, ibuprofen, and suprofen exhibit lower levels of covalent binding (Bolze et al., 2002). The chemical reactivity of acyl glucuronides (as measured by glycation of albumin or a trapping agent such as the dipeptide phenylalanine lysine) is highly correlated with its rate of isomerization whereby the xenobiotic sequentially migrates from the initial 1-*O*-β position to the 2-, 3-, and 4-positions (which can be in either the α- or β-configuration) (Wang et al., 2004). It is only after the xenobiotic migrates from the 1-position that the glucuronide moiety can transiently open to its hemiacetal form and form a Schiff base with lysine residues. When incubated in protein-free phosphate buffer at pH 7.4, those acyl glucuronides with a half-life of less than 30 minutes (with the loss of the 1-*O*-β isomer occurring by a combination of isomerization and hydrolysis) include the acyl glucuronides of the particularly hepatotoxic NSAIDs zomepirac and tolmetin. Isomerization is slowed by the addition of one or two substituents on the α-carbon (next to the carboxylic acid moiety), which correlates with their reduced toxicity. However, a direct correlation between the ability of acyl glucuronides to give rise to covalent adducts with proteins such as albumin and their ability to cause drug-related toxicity has not been firmly established, and other mechanisms may come into play. For instance, diclofenac is still a widely used drug in spite of the fact that its acyl glucuronide is very reactive, whereas zomepirac, which is less reactive than these other drugs, was withdrawn from the market in 1983 (Chen et al., 2006; Regan et al., 2010).

Neoantigens formed by binding of acyl glucuronides to protein might be the cause of rare cases of NSAID-induced immune hepatitis. Covalent adducts with proteins in the liver, kidneys, colon, small intestine, skeletal muscle, and bladder were detected in rats administered diflunisal, and in the liver, lungs, and spleen of rats administered diclofenac (Shipkova et al., 2003). Covalent binding of acyl glucuronides to proteins can be selective, with diclofenac acyl glucuronide forming adducts with dipeptidyl peptidase in the rat liver, and with aminopeptidase N and sucrase-isomaltase in rat intestine (Shipkova et al., 2003). Human and rat liver UGTs are themselves targets of adducts formed by ketoprofen acyl glucuronide, which may cause nonspecific irreversible inhibition (Shipkova et al., 2003). Both acyl glucuronides and acyl-CoA thioesters can transacylate proteins either directly or after their conversion to GSH adducts. Based on in vitro trapping studies with *N*-acetylcysteine (NAC) as the nucleophile, the reactivity of acyl-CoA thioesters is dependent on the substitution of the α-carbon and β-carbon of the xenobiotic (Grillo, 2011). The addition of methyl groups to the α-carbon and/or oxygen to the β-carbon decreases the reactivity of acyl-CoA thioesters just as it decreases the reactivity of acyl glucuronides. In terms of binding to NAC (an indicator of transacylation reactivity), acyl-CoA thioesters and their corresponding acyl-GSH thioesters can be orders of magnitude more reactive than acyl glucuronides, for which reason the formation of acyl-CoA thioesters may contribute to the hepatotoxicity of NSAIDs and other carboxylic acid–containing drugs (Grillo, 2011).

Knights et al. (2007) reviewed the ability of acyl-CoA conjugates of acidic drugs to cause mitochondrial toxicity by interruption of the mitochondrial β-oxidation of fatty acids, which is dependent on their conversion to fatty acyl-CoA thioesters. Xenobiotic-CoA conjugates that are resistant to hydrolysis and are not conjugated with amino acids (e.g., valproic acid) can sequester the pool of mitochondrial CoA and disrupt fatty acid β-oxidation, which are key events in the hepatotoxicity of valproic acid. Valproic acid is metabolized in mitochondria (major pathway) and microsomes (where it is dehydrogenated to 4-ene-valporic acid by CYP2C9 [Fig. 6-53]). In mitochondria, valproic acid is converted to an acyl-CoA thioester that in turn is converted to metabolites that resemble intermediates in the β-oxidation of fatty acids, as shown in Fig. 6-63. Valproic acid is present in mitochondria primarily in the form of its acyl-CoA thioester, which is too polar to diffuse out of the mitochondrion. Taken together, these studies suggest that the conversion of carboxylic acid–containing drugs to acyl-CoA thioesters can play an important role in cell toxicity by causing mitochondrial damage (by depleting CoA and disrupting fatty acid β-oxidation) or by binding covalently to proteins (either directly or following conversion to acyl-GSH thioesters) (Knights et al., 2007; Grillo, 2011).

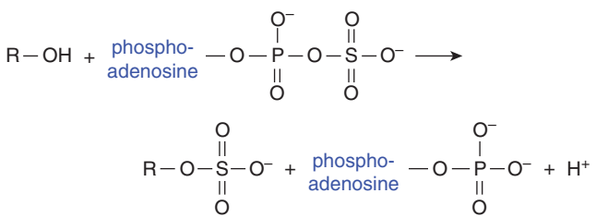
The intrinsic reactivity of acyl glucuronides and acyl-CoA thioesters is not the only factor that contributes to the toxicity of carboxylic acid–containing drugs and metabolites. Extrinsic factors also influence the potential for toxicity, such as dose/exposure, disposition of the parent drug and its metabolites, hydrolysis of acyl glucuronides in the gut (or even in plasma), and reexposure to the aglycone via enterohepatic circulation, transport mechanisms for the efflux of acyl glucuronides from liver into bile or blood, and, perhaps most importantly, targets of these reactive species. Dose or daily body burden is a concern for many acidic drugs (e.g., NSAIDs) because hundreds of milligrams—or even gram quantities—are consumed daily. The reactivity of these metabolites can be assessed with relatively simple in vitro techniques as described above. Intrinsic reactivity can be predicted, to some extent, with structural alerts; the substitution pattern of the α-carbon is particularly informative. Transport proteins also play a crucial role in the disposition of acidic drugs and their acyl glucuronides. MRP2 and MRP3 play critical roles in the efflux of acyl glucuronides into bile and blood, respectively. Shifts in the vectoral transport of these acyl glucuronides may dictate whether toxicity is limited to the cells in which they are formed or whether these reactive metabolites enter bile where they can cause damage to biliary endothelial cells or enter the systemic circulation where they can cause damage to other

tissues or blood. Just as efflux transporters are crucial for transporting these anionic compounds into blood, uptake transporters (OATPs) are involved in tissue-mediated uptake of acyl glucuronides as well as active renal elimination. Expression patterns of certain transporters may predispose or preclude certain cell types to toxicities caused by acyl glucuronides. It should be noted that unlike acyl glucuronides, acyl-CoA thioester metabolites are not transporter substrates and do not leave the cell in which they are formed. This suggests that toxicities caused by acylation of proteins by acyl-CoA thioester metabolites are restricted to the cell where the metabolite is formed (e.g., formed in the hepatocyte and causes hepatotoxicity). In the case of acyl glucuronides and acyl-CoA thioesters, the identity of the protein adducted may determine whether or not these acidic drugs are toxic.

Sulfonation

Many of the xenobiotics and endogenous substrates that undergo *O*-glucuronidation also undergo *O*-sulfonation, as illustrated in Fig. 6-39, for acetaminophen (Mulder, 1981; Paulson et al., 1986). Sulfonation generally produces a highly water-soluble sulfuric acid ester (see Table 6-3). The reaction is catalyzed by sulfotransferases (SULTs), a large multigene family of enzymes that are widely distributed throughout the body (Chen et al., 2015a). In mammals, there are two major classes of SULTs: (1) membrane-bound SULTs in the Golgi apparatus and (2) soluble SULTs in the cytoplasm (Gamage et al., 2006). The membrane-bound SULTs are responsible for the sulfonation of various glycosaminoglycans, proteins, and peptides. At least five different Golgi-resident *N*-acetylglucosamine 6-*O*-sulfotransferases have been identified in humans (Grunwell and Bertozzi, 2002). Brachymorphic mice, which have a global defect in SULT activity due to an impairment in the synthesis of PAPS, the cofactor for sulfonation (see below in this section), are undersized because of their defective sulfonation of glycosaminoglycans and proteoglycans, such as heparin and chondroitin, which are important components of cartilage. These particular sulfonation reactions are catalyzed by membrane-bound SULTs, which play no known role in xenobiotic sulfonation (Wang and James, 2006). This section focuses on the cytosolic SULTs, which are known for the sulfonation of various drugs, mutagens, flavonoids, and other xenobiotics, as well as endogenous substrates such as bile acids, thyroid hormones, catecholamine neurotransmitters, and steroids.

The cofactor for the sulfonation reaction is 3′-phosphoadenosine-5′-phosphosulfate (PAPS), the structure of which is shown in Fig. 6-57. The sulfonation of aliphatic alcohols and phenols, R-OH, proceeds as follows:



Sulfonation involves the transfer of sulfonate, not sulfate (i.e., SO_3^-, not SO_4^-) from PAPS to the xenobiotic. The reaction catalyzed by a SULT enzyme involves simultaneous binding of PAPS and substrate (S), and can be depicted as follows:

$$\text{Enzyme} + \text{PAPS} + \text{S} \rightarrow [\text{Enzyme-PAPS-S}] \rightarrow [\text{Enzyme-PAP}] + \text{S-sulfonate}$$

Sulfonation of the substrate involves the conversion of PAPS to PAP. Dissociation of PAP from the SULT enzyme is relatively slow and generally determines the overall rate of sulfonation (i.e., dissociation of PAP is the rate-limiting step in the catalytic cycle). In addition to PAPS, several sulfonated compounds, such as 4-nitrophenyl sulfate, can support the sulfonation of substrates by converting PAP to PAPS in the active site of SULT, which effectively bypasses the rate-limiting step in sulfonation. For this reason, sulfonation reactions supported by both PAPS and 4-nitrophenyl sulfate are an order of magnitude faster than those supported by PAPS alone (Duffel and Jakoby, 1981).

PAPS is synthesized from inorganic sulfate (SO_4^{2-}) and ATP in a two-step reaction. The first reaction is catalyzed by ATP sulfurylase, which converts ATP and SO_4^{2-} to adenosine-5′-phosphosulfate (APS) and pyrophosphate. The second reaction is catalyzed by APS kinase, which transfers a phosphate group from ATP to the 3′-position of APS. These two enzymes are domains on a single enzyme called PAPS synthetase or PAPSS. Mammals express two forms of PAPS synthetase, PAPSS1 and PAPSS2 (Coughtrie, 2016). Mutations in PAPSS2 are linked to rare musculoskeletal and endocrine disorders in humans (Coughtrie, 2016). The major source of sulfate required for the synthesis of PAPS is derived from cysteine through a complex oxidation sequence. Because the concentration of free cysteine is limited, the cellular concentrations of PAPS (4 to 80 μM) are considerably lower than those of UDPGA (200 to 350 μM) and GSH (5 to 10 mM). This topic has been thoroughly reviewed, and is outside the scope of this chapter (Klaassen and Boles, 1997). The relatively low concentration of PAPS limits the capacity for xenobiotic sulfonation. In general, sulfonation is a high-affinity but low-capacity pathway of xenobiotic conjugation, whereas glucuronidation is a low-affinity but high-capacity pathway. Acetaminophen is one of the several xenobiotics that are substrates for both SULTs and UGTs (see Fig. 6-39). The relative amount of sulfonate and glucuronide conjugates of acetaminophen is dependent on dose. At low doses, acetaminophen sulfonate is the main conjugate formed due to the high affinity of SULTs. As the dose of acetaminophen increases, the proportion of acetaminophen conjugated with sulfonate or glucuronic acid decreases and increases, respectively. In some cases, even the absolute amount of xenobiotic conjugated with sulfonate can decrease at high doses due to substrate inhibition of SULT, which can occur by two mechanisms. First, at high concentrations, substrates can bind to the Enzyme-PAP complex (rather than the Enzyme-PAPS complex) and form a dead-end complex. Second, two substrates can bind simultaneously to SULT either with both substrates in the large substrate-binding (active) site or with one substrate in the active site and another in an allosteric binding site (Chen et al., 2015a). Binding of two different substrates to a single SULT can alter the regiospecificity of sulfonation. For example, in the absence of other chemicals, SULT2A1 catalyzes the sulfonation of 17α-ethinylestradiol in the 3-position, but in the presence of high concentrations of celecoxib this switches to sulfonation in the 17-position (Cui et al., 2004).

Table 6-23 lists some examples of xenobiotics and endogenous compounds that are sulfonated without prior biotransformation by oxidative enzymes. An even greater number of xenobiotics are sulfonated after a hydroxyl group is exposed or introduced during hydrolytic or oxidative biotransformation. Phenols and aliphatic alcohols (which are often the products of oxidative or hydrolytic biotransformation) are converted to *O*-sulfonates, and these represent the largest groups of substrates for SULTs. However, in some cases, SULTs can form *N*-sulfonates, otherwise known as sulfamates. For example, aniline and 2-aminonaphthalene, two

Properties of the Human Cytosolic Sulfotransferases (SULTs)

HUMAN SULT	POLYMORPHIC?*	TISSUE DISTRIBUTION	MAJOR SUBSTRATES†,‡
SULT1A1	Yes*** *1–*4	Liver, platelets, placenta, adrenal gland, endometrium, colon, small intestine, leukocytes, brain	**4-Nitrophenol**, acetaminophen, apomorphine, 4-cresol, dopamine, epinephrine, 17β-estradiol (and other phenolic steroids), 4-ethylphenol, genistein, *N*-hydroxy-PhIP, minoxidil, morphine, naloxone, 2-naphthol (and other phenols), 2-nitropropane, numerous aromatic amines, hydroxylamines, hydroxamic acids, and benzylic alcohols, T2, T3, troglitazone
SULT1A2	Yes *1–*6	Liver, kidney, brain, gastrointestinal tract, leukocytes, bladder tumors	4-Nitrophenol, *N*-hydroxy-2-acetylaminofluorene, minoxidil, morphine, naloxone, 2-naphthol, various aromatic hydroxylamines and hydroxamic acids
SULT1A3	Yes *1–*4	Small intestine and colon, liver, platelets, placenta, brain, leukocytes, fetal liver	**Dopamine**, albuterol, dobutamine, 1-hydroxymethylpyrene, minoxidil, morphine, 4-nitrophenol, norepinephrine, salbutamol, vanillin
SULT1A4		Liver, pancreas, colon, brain	Likely similar to SULT1A3
SULT1B1		Gastrointestinal tract, liver, leukocytes, skeletal muscle	Benzylic alcohols, dopamine, 4-nitrophenol, T2, T3, r-T3, T4
SULT1C2	Yes *1–*5	Kidney, gastrointestinal tract, thyroid gland, heart, fetal lung and kidney	Aromatic hydroxylamines, *N*-hydroxy-2-acetylaminofluorene, 4-nitrophenol, thyroid hormones
SULT1C3		Appendix, lymph nodes, thymus, adrenal gland, fetal liver	Unknown
SULT1C4		Kidney, ovary, spinal cord, fetal kidney and lung	Bisphenol-A, diethylstilbestrol, estrone, 1-hydroxymethylpyrene, *N*-hydroxy-2-acetylaminofluorene, 4-nitrophenol, nonylphenol, 4-octylphenol
SULT1D1		Not characterized	
SULT1E1		Liver, small intestine, endometrium, heart, adrenal gland, mammary epithelial cells, and fetal liver, lung, and kidney	**17β-Estradiol**, dehydroepiandrosterone, diethylstilbestrol, equilenin, estrone, ethinyl estradiol, 2- and 4-hydroxyestrone, 2- and 4-hydroxyestradiol, 4-hydroxylonazolac, 1-naphthol, naringenin, pregnenolone, raloxifene, tamoxifen, thyroid hormones
SULT2A1	Yes *1–*3	Liver, adrenal gland, ovaries, prostate, small intestine, kidney, brain	**Dehydroepiandrosterone (DHEA)**, afitoxifene, bile acids, budesonide, buprenorphine, estradiol (and other hydroxysteroids), hycanthone, 1-hydroxymethylpyrene, 6-hydroxymethylbenzo[*a*]pyrene, 4-hydroxytamoxifen, pregnenolone, raloxifene, testosterone (and other androgens)
SULT2B1		Tongue, placenta, liver, prostate, trachea, skin, skeletal muscle, spleen, thymus, kidney, ovary, adrenal gland, gastrointestinal tract	**Cholesterol**, dehydroepiandrosterone, pregnenolone and other oxysterols and hydroxysteroids
SULT4A1		Brain	Estrone, 2-naphthol, 2-naphthylamine, 4-nitrophenol, T3, T4
SULT6B1		Testis, kidney	Unknown

**Data from Lindsay et al. (2008).*

†Substrates in bold are reported to be selective probe substrates for the SULT listed. Data from Coughtrie and Fisher (2003), Blanchard et al. (2004), Bradley and Benner (2005), Gamage et al. (2006), Wang and James (2006), Lindsay et al. (2008), Riches et al. (2009), and Salman et al. (2009).

‡T4 is thyroxine. T2 and T3 are di- and tri-iodothyronine. r-T3 is reverse tri-iodothyronine.

aromatic amines, can undergo sulfonation to the corresponding sulfamates, which involves formation of a nitrogen-sulfur bond ($R–NH_2 + PAPS \rightarrow R–NH–SO_3H + PAP$). The primary amines in cisapride and DPC423 (an inhibitor of coagulation factor Xa) can also be directly *N*-sulfonated to sulfamates. *N*-Oxides and hydroxylamines can also be *O*-sulfonated by SULTs. The *N*-oxide group in minoxidil can be sulfonated to form a pharmacologically active metabolite, and in this case the sulfonate group is attached to the oxygen atom, not the nitrogen atom ($R_1R_2R_3 - N^+ - O^- + PAPS \rightarrow R_1R_2R_3 - N^+ - O - SO_3^- + PAP$).

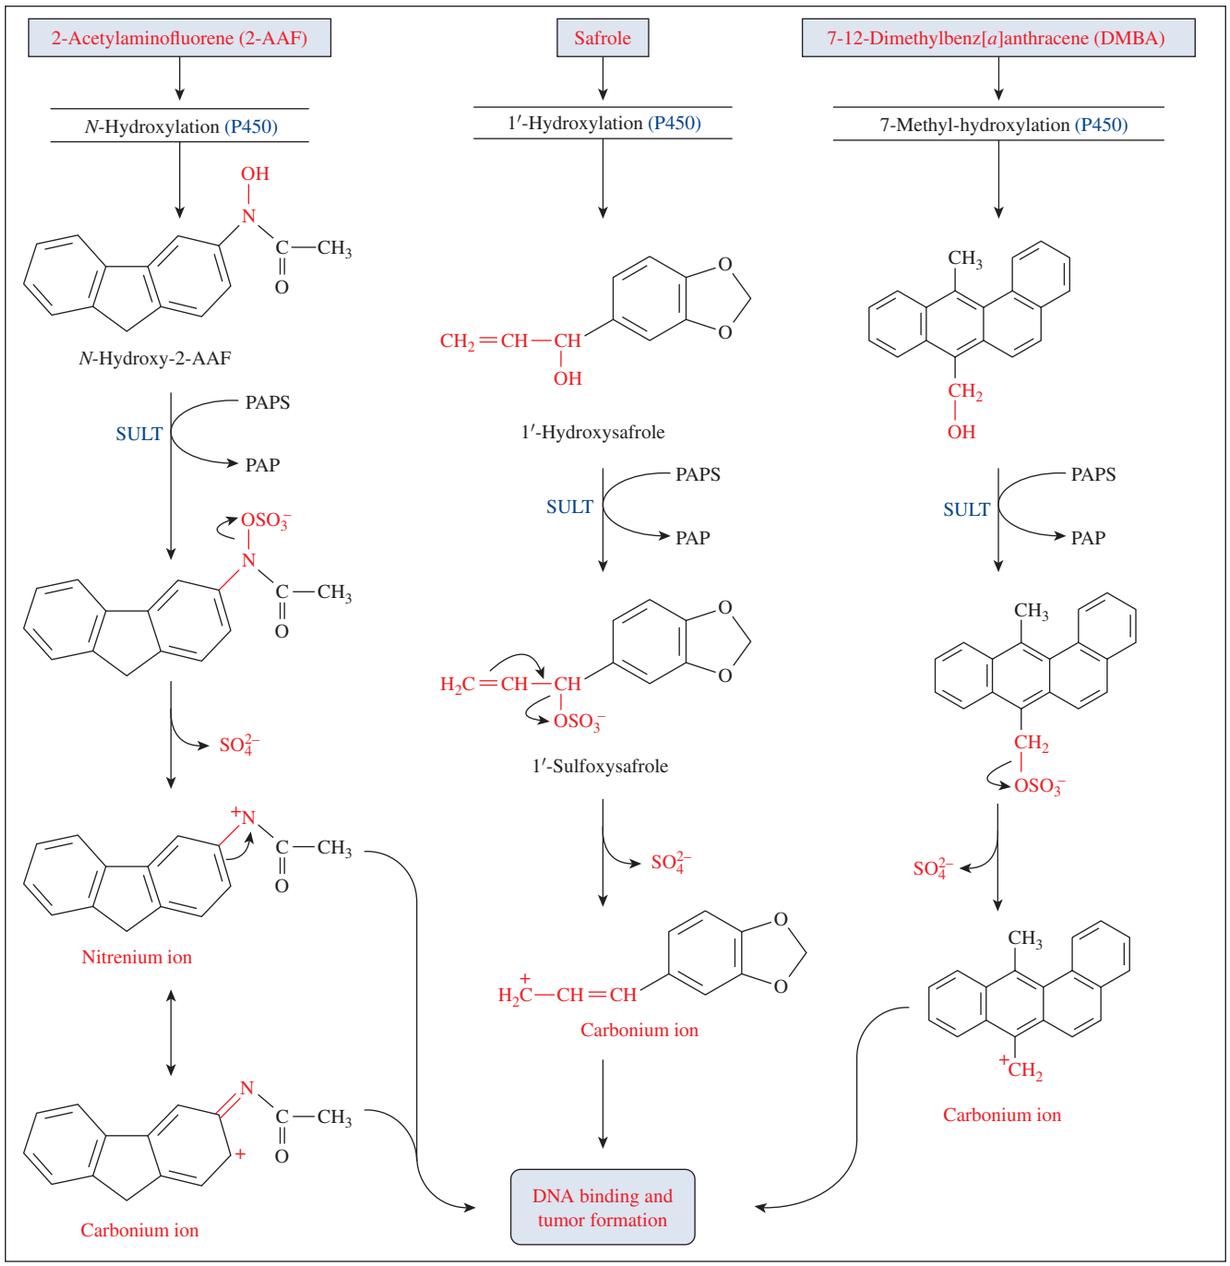

Figure 6-64. *Role of sulfonation in the generation of tumorigenic metabolites (nitrenium or carbonium ions) of 2-acetylaminofluorene, safrole, and 7,12-dimethylbenz[a]anthracene (DMBA).*

Similarly, the *N*-hydroxy group in *N*-hydroxy-2-aminonaphthalene and hydroxy-2-acetylaminofluorene (NOH-AAF) can be sulfonated, as shown for NOH-AAF in Fig. 6-64. In all cases, the conjugation reaction involves nucleophilic attack of oxygen or nitrogen on the electrophilic sulfur atom in PAPS with cleavage of the phosphosulfate bond.

Sulfonation and glucuronidation are often viewed as equal solutions to the problem of biotransforming xenobiotics and their phase 1 metabolites to water-soluble conjugates that can be readily eliminated from the body. However, in terms of forming reactive and potentially toxic/carcinogenic metabolites, sulfonation and glucuronidation differ in several aspects. As discussed in the previous section "Glucuronidation," formation of reactive metabolites that undergo glucuronidation is a concern with carboxylic acid–containing xenobiotics, which can be converted to potentially reactive acyl glucuronides, but it is not a concern with aliphatic alcohols and phenols that undergo *O*-glucuronidation. Acidic drugs are not conjugated by SULTs; hence, the conversion of carboxylic acid–containing xenobiotics to potentially reactive acyl sulfonates is not a concern. However, in contrast to *O*-glucuronidation, *O*-sulfonation can produce reactive and potentially toxic/carcinogenic metabolites. This is because addition of a sulfonate moiety to the oxygen atom of an alcohol, phenol, or *N*-hydroxylamine produces a sulfate group that, being a good leaving group, can dissociate to form a

carbon- or nitrogen-centered anion (i.e., a carbonium or nitrenium ion), as shown below:

$$R - OH(\text{alcohol or phenol}) \rightarrow R - O - SO_3^- \rightarrow R^+(\text{carbonium ion}) + {}^-O - SO_3^-(\text{sulfate})$$

$$R - NH - OH(\text{hydroxylamine}) \rightarrow R - NH - O - SO_3^- \rightarrow R - NH^+(\text{nitrenium ion}) + {}^-O - SO_3^-(\text{sulfate})$$

Examples of xenobiotics that are converted to reactive metabolites by pathways that involve *O*-sulfonation are shown in Fig. 6-64. *O*-Sulfonation plays an important role in the activation of aromatic amines, such as the hepatocarcinogen 2-acetylaminofluorene (2-AAF), methyl-substituted PAHs, such as the lung and skin carcinogen dimethylbenzanthracene (DMBA), and safrole, a hepatotumorigen. Activation of 2-AAF involves CYP-dependent *N*-hydroxylated to a hydroxylamine (NOH-AAF) followed by *O*-sulfonation to a conjugate that can lose the sulfate moiety to form a reactive nitrenium ion (which can rearrange to form a carbonium ion), as shown in the first panel of Fig. 6-64. The same reactions (i.e., *N*-hydroxylation followed by *O*-sulfonation) are the final steps in the metabolic activation of the hepatotumorigen 2,6-dinitrotoluene, as shown in Fig. 6-16. To exert its tumorigenic effect in rodents, safrole must be hydroxylated by CYP to 1′-hydroxysafrole, which is then sulfonated to the electrophilic and tumor-initiating metabolite 1′-sulfooxysafrole, as shown in the middle panel of Fig. 6-64. 1′-Hydroxysafrole is a more reactive and a more potent hepatotumorigen than safrole due to its ability to form a reactive carbonium ion. Two lines of evidence support a major role for sulfonation in the hepatotumorigenic effect of 1′-hydroxysafrole. First, the hepatotumorigenic effect of 1′-hydroxysafrole can be inhibited by treating mice with the SULT inhibitor pentachlorophenol (discussed later in this section). Second, the hepatotumorigenic effect of 1′-hydroxysafrole is markedly reduced in brachymorphic mice, which have a diminished capacity to sulfonate xenobiotics because of a genetic defect in PAPS synthesis (Boberg et al., 1983). A similar pathway, namely, benzylic hydroxylation followed by *O*-sulfonation, converts DMBA to a sulfate conjugate that can lose sulfate to form a reactive carbonium ion, as shown in the third panel in Fig. 6-64. The sulfonate conjugates of benzylic and allylic alcohols, aromatic hydroxylamines, and hydroxamic acids (including those in cooked meat) are short-lived electrophiles capable of reacting with nucleophilic substances including proteins and DNA (Wang and James, 2006). In addition to 1′-hydroxysafrole, the benzylic alcohol of DMBA, and NOH-AAF, sulfonation has been implicated in converting 1-hydroxymethylpyrene (1-HMP), and the cooked food mutagen *N*-hydroxy-2-amino-1-methyl-6-phenylimidazo(4,5-*b*) pyridine (*N*-OH-PhIP) to electrophilic nitrenium or carbocation intermediates linked to mutagenesis or tumorigenesis (Wang and James, 2006). In rats, gender differences in the tumorigenesis of various aromatic amines, arylhydroxamic acids, and the benzylic alcohols of polycyclic aromatic hydrocarbons have been linked to gender differences in the expression of multiple SULT enzymes (discussed later in this section) (Coughtrie, 2016).

Benzylic hydroxylation and subsequent *O*-sulfonation are key steps in the metabolic activation of safrole and DMBA, as shown in Fig. 6-64. These same pathways are also responsible for activating nevirapine to a reactive metabolite in skin, which is the underlying cause of skin rashes (red blotches, itchy lumps, and/or speckles) in about one in five people starting nevirapine treatment, which qualifies as a serious (life-threatening) idiosyncratic reaction in approximately 0.3% of patients on this antiretroviral drug. Covalent binding to protein and rash can be induced by nevirapine in the human and rat skin, but not in the mouse skin, which does not sulfonate the benzyl alcohol metabolite of nevirapine. In the human and rat skin, covalent binding and rash caused by nevirapine or its benzyl alcohol metabolite can be blocked by local application of 1-phenyl-1-hexanol, a SULT inhibitor (Uetrecht and Naisbitt, 2013). These studies underscore the importance of SULTs in extrahepatic tissues in the formation of reactive metabolites.

Although carboxylic acids can be conjugated with glucuronic acid, they cannot be conjugated with sulfonate. However, a number of carboxylic acids, such as benzoic acid, naphthoic acid, naphthylacetic acid, salicylic acid, and naproxen, are inhibitors of SULTs (Rao and Duffel, 1991). Pentachlorophenol and 2,6-dichloro-4-nitrophenol are potent SULT inhibitors because they bind to the enzyme but cannot initiate a nucleophilic attack on PAPS due to the presence of electron-withdrawing substituents in the *ortho*- and *para*-positions on the aromatic ring. In addition to these direct inhibitors, salicylamide and 1-phenyl-1-hexanol, both of which are SULT substrates that undergo rapid sulfonation, are used in vitro and in animals to cause generalized inhibition of SULT activity by depleting PAPS, which was exploited, for example, in studies of the role of SULT in an idiosyncratic reaction to nevirapine (namely skin rash), as discussed earlier in this section. Inhibition of SULTs can occur with exposure to drugs such as mefenamic acid, salicylic acid, clomiphene, danazol, environmental chemicals, such as hydroxylated PCBs, hydroxylated PAHs, pentachlorophenol, triclosan, and bisphenol A, and dietary constituents, such as catechins, colorants, phytoestrogens, and flavonoids. Adverse effects on human health can potentially result from SULT inhibition, such as the thyroid hormone disruption, that occurs with exposure to hydroxylated PCBs (Wang and James, 2006). In contrast, given that some sulfonate conjugates are chemically reactive (discussed earlier in this section), inhibition of their formation may be protective. There are a few reports of drug–drug interactions due to SULT inhibition. It has been reported that the sulfonation rates of both acetaminophen and salicylamide are decreased when these drugs are administered together, and dapsone and lamivudine have been found to decrease acetaminophen sulfonation (Wang and James, 2006). Coadministration of acetaminophen with ethinyl estradiol increases its AUC by up to 54% and decreases the AUC of ethinyl estradiol sulfate by about 40%, indicating that acetaminophen may directly inhibit one or more SULTs (Rogers et al., 1987). Drug–drug interactions involving induction of SULT are detailed later in this section.

Sulfonate conjugates of xenobiotics are excreted mainly in urine. Those excreted in bile may be hydrolyzed by aryl sulfatases present in gut microbiota, which contributes to the enterohepatic circulation of certain xenobiotics. Sulfatases are also present in the endoplasmic reticulum and lysosomes, where they primarily hydrolyze sulfonates of endogenous compounds, presumably in a manner analogous to that described for microsomal β-glucuronidase (Dwivedi et al., 1987) (see comments on egasyn in the section "Carboxylesterases"). Like glucuronide conjugates, some sulfonate conjugates are substrates for further biotransformation. For instance, the 7- and 4-sulfates of daidzein and genistein can be sulfonated by SULT1E1 to disulfates (Nakano et al., 2004). Other examples include the oxidation of sulfonate conjugates of testosterone and estrogens. Dehydroepiandrosterone-3-sulfate is 16α-hydroxylated by CYP3A7, the major CYP enzyme expressed in the human fetal liver (Ingelman-Sundberg et al., 1975; Kitada et al., 1987; Ohmori et al., 1998). CYP2C12, which is expressed in female but not male rats, catalyzes the oxidation of a steroid *di*-sulfate (namely, 5α-androstane-3α,17β-diol-3,17-disulfate) (Ryan et al., 1984). Sulfonation facilitates the deiodination of T4 and

triiodothyronine (T3) and can determine the rate of elimination of thyroid hormones in some species. Efavirenz sulfate is conjugated with GSH in rodents but not primates and accounts for the rodent-specific nephrotoxicity of this antiretroviral drug, as described in the section "Glutathione Conjugation."

Multiple SULTs have been identified in all mammalian species examined and they are arranged into gene families that share at least 45% amino acid sequence identity, which are subdivided into subfamilies that are at least 60% identical (Blanchard et al., 2004; Gamage et al., 2006). The SULTs expressed in mammals belong to six families (SULT1 to SULT6). Humans express SULT only in families 1, 2, 4, and 6. SULT3 is expressed only in mice and rabbits, whereas SULT5 is expressed only in mice (Chen et al., 2015a). SULT1 and SULT2 are the only gene families subdivided into multiple subfamilies: five in the case of SULT1 (SULT1A to SULT1E), and two in the case of SULT2 (SULT2A and SULT2B). As shown in Table 6-23, humans express 14 SULTs, namely, SULT1A1, 1A2, 1A3, 1A4, 1B1, 1C2, 1C3, 1C4, 1D1, 1E1, 2A1, 2B1, 4A1, and 6B1. Human SULT4A1 is expressed in the brain and SULT6B1 is expressed in the testis and kidney. Their role in xenobiotic sulfonation is largely unknown, as is their presumptive physiological function. Sulfonation of xenobiotics is catalyzed by various members of the SULT1 and SULT2 families. SULT1 enzymes catalyze the sulfonation of phenols, isoflavones, the procarcinogen NOH-AAF, endogenous compounds such as 17β-estradiol (including its glucuronide conjugate; see the section "Glucuronidation and Formation of Acyl-CoA Thioesters"), and other steroids, thyroid hormones, endogenous catecholamines, and eicosanoids. The SULT2 enzymes catalyze the sulfonation of the 3β-hydroxy groups of steroids (in contrast to UGTs, which glucuronidate the 3α-hydroxy groups of steroids), bile acids, benzylic alcohols of PAHs, and other primary and secondary alcohols.

SULTs are expressed in a wide range of tissues. Based on quantitative immunoblotting techniques, Riches et al. (2009) quantified five of the major SULT enzymes involved in xenobiotic sulfonation (SULT1A1, 1B1, 1E1, 2A1, and 1A3) in cytosol from the human liver, small intestine, kidney, and lung. In human liver cytosol, the rank order of protein expression was as follows: SULT1A1 (53%) > 2A1 (27%) > 1B1 (14%) > 1E1 (6%) > 1A3 (0%). The kidney was similar to the liver inasmuch as SULT1A1 was the major enzyme expressed (40%), followed by SULT1B1 (31%) > 1A3 (28%) > 2A1 (1%) > 1E1 (0%). In the small intestine, SULT1B1 and SULT1A3 were most highly expressed enzymes (36% and 31%, respectively), followed by SULT1A1 (19%) > 1E1 (8%) > 2A1 (6%). Lastly, SULT1E1 protein was most highly expressed in lung (40%), followed by SULT1A1 (20%) > 1A3 (19%) > 1B1 (12%) > 2A1 (9%). In humans, SULTs are predominantly expressed in extrahepatic tissues. Based on microarray analysis of 79 human tissues, mRNA encoding most SULT enzymes was detected in the liver but in no case did the liver have the highest levels of an individual SULT mRNA (Chen et al., 2015a). Further details on the tissue expression of SULTs are summarized in Table 6-23.

Our current understanding of the multiplicity of SULTs is based on genome sequencing, as is the case with all other classes of xenobiotic biotransforming enzymes. Two prior classifications that provided insight into the multiplicity of SULTs are briefly described here for historical reasons. In human liver cytosol, SULT activity toward phenolic compounds, the so-called phenol sulfotransferase or PST, was found to exist in two forms that could be distinguished by their thermal stability; hence, they were known as TS-PST (*thermally stable*) and TL-PST (*thermally labile*) (Weinshilboum, 1992a; Weinshilboum et al., 1997). It is now known that TS-PST largely reflects the activity of SULT1A1 and SULT1A2, whereas TL-PST largely reflects the activity of SULT1A3 and SULT1A4 (Gamage et al., 2006).

Historically, the SULT enzymes were previously categorized into five classes based on their catalytic activity. These five functional classes were as follows: *arylsulfotransferase*, which sulfonates numerous phenolic xenobiotics; *alcohol SULT*, which sulfonates primary and secondary alcohols including nonaromatic hydroxysteroids (for which reason these enzymes are also known as hydroxysteroid SULTs); *estrogen SULT*, which sulfonates estrone and other aromatic hydroxysteroids; *tyrosine ester SULT*, which sulfonates tyrosine methyl ester and 2-cyanoethyl-*N*-hydroxythioacetamide; and *bile salt SULT*, which sulfonates conjugated and unconjugated bile acids. The *arylsulfotransferase* and *estrogen SULT* are composed largely of SULT1 enzymes, which catalyze the sulfonation of phenolic xenobiotics, catechols, and aromatic (phenolic) steroids. The *alcohol SULT* and *bile salt SULT* are composed largely of SULT2 enzymes, which catalyze the sulfonation of a variety of primary and secondary alcohols, bile acids, and hydroxysteroids (such as DHEA).

Genetic polymorphisms have been described for human SULTs. They can affect SULT function and/or expression in a tissue-specific manner. For example, an allelic variant of SULT1A1 known as SULT1A1*2 ($Arg_{213} \rightarrow His_{213}$) is associated with decreased expression in platelets but not the liver, and decreased thermal stability (Glatt and Meinl, 2004a). This particular genetic polymorphism is common in both Caucasians and Nigerians (with an allele frequency of 31% and 37%, respectively), and is correlated with interindividual variation in the sulfonation of acetaminophen. SULT1A1 catalyzes the sulfonation of the 4-hydroxymetabolite of tamoxifen, a metabolite identified as a potent inducer of apoptosis in certain breast cancer cell lines. Contrary to expectation, the lower activity SULT1A1*2 allele did not improve the efficacy of tamoxifen in breast cancer patients by decreasing clearance of 4-hydroxytamoxifen. It was the wild-type (*1) allele that, paradoxically, was correlated with improved outcomes with tamoxifen therapy (Nowell and Falany, 2006). Human SULT1B1, like the corresponding enzyme in other species, catalyzes the sulfonation of thyroid hormones, 2-naphthol, and dopamine. SULT1B1 levels in human liver cytosol vary widely, possibly due to polymorphisms (e.g., $Glu_{186} \rightarrow Gly_{186}$ and $Glu_{204} \rightarrow Asp_{204}$) (Glatt and Meinl, 2004a). Polymorphisms with consequences for the bioactivation of xenobiotics have been reported. For instance, the human SULT1A*Arg (*1) allelozyme expressed in *S. typhimurium* is 12- to 350-fold more active in the sulfonation of 2-acetylamino-4-hydroxyaminotoluene, 2-nitropropoane, 2,4-dinitrobenzylalcohol, (–)-1-(α-hydroxyethyl) pyrene, and 1-hydroxymethlpyrene to mutagens than are cells expressing SULT1A1*His (Gamage et al., 2006). Enantioselective sulfonation of promutagens has been reported, as in the case of 1-(α-hydroxyethyl) pyrene, for which SULT2A1 exhibits a 15-fold preference for the (+)-enantiomer, and SULT1E1 exhibits a 160-fold preference for the (–)-enantiomer (Gamage et al., 2006).

Human SULT1E1 has been identified as a high-affinity estrogen SULT. SULT1A1 also catalyzes the sulfonation of estrogens, such as 17β-estradiol, but it does so with a much lower affinity than does SULT1E1. The sulfonation of ethinyl estradiol in human hepatocytes is inducible by rifampin (Li et al., 1999). In addition to the human liver, SULT1E1 is expressed in the placenta, breast, brain, testes, adrenal glands, and uterine tissue. SULT1E1 has been studied in SULT1E1-deficient mice, and it has been shown that these mice had spontaneous fetal loss caused by placental thrombosis, which was reversible by administration of antiestrogens (Gamage et al., 2006).

SULT2A1 is the human alcohol SULT long known as DHEA-ST (for its ability to sulfonate dehydroepiandosterone [DHEA]). In addition to DHEA, substrates for SULT2A1 include steroid hormones, bile acids, and cholesterol. Furthermore, SULT2A1 converts several procarcinogens to electrophilic metabolites, including hydroxymethyl PAHs, NOH-AAF, and 1-hydoxysafrole, as shown in Fig. 6-64. The thermal stability of SULT2A1 is intermediate between that of the four phenol SULTs (SULT1A1/2 and SULT1A3/4), and the enzyme is resistant to the inhibitory effects of 2,6-dichloro-4-nitrophenol. In humans, SULT2A1 selectively catalyzes the *N*-sulfonation of quinolone drugs, such as ciprofloxacin, moxifloxacin, garenoxacin, and other amine drugs such as desipramine and metoclopramide (Senggunprai et al., 2009). SULT2A1 is not expressed in blood platelets, but the activity of this enzyme has been measured in human liver cytosol. It is also expressed in adrenal cortex, brain, and intestine (Blanchard et al., 2004). SULT2A1 is bimodally distributed, possibly due to a genetic polymorphism that apparently lies outside of the coding region, and perhaps outside of the SULT2A1 gene itself, with a high-activity group composed of about 25% of the population (Glatt and Meinl, 2004a). Several SULT2A1 SNPs have been identified, but the underlying basis for the high-activity group remains to be determined as these polymorphisms appear to be too rare to explain the bimodal distribution.

Human SULT2B1 is also a DHEA sulfotransferase. It is expressed in the placenta, prostate, and trachea. The SULT2B1 gene can be transcribed from one of the two exons, both of which contain coding sequences; hence, two forms of SULT2B1 (known as 2B1_v1 and 2B1_v2) with different N-terminal amino acid sequences can be transcribed by alternate splicing of precursor mRNA. This situation is analogous to the alternative splicing of multiple exons 1 in the UGT1 gene family (see Fig. 6-61). SULT2B1_v1 catalyzes the sulfonation of pregnenolone, and SULT2B1_v2 can catalyze the sulfonation of both pregnenolone and cholesterol (Blanchard et al., 2004).

Extrapolation of animal data with regard to biotransformation by SULTs is confounded by the number of SULTs, the expression pattern of SULTs, and pronounced gender differences in rodents (Gamage et al., 2006; Coughtrie, 2016). For instance, expression of SULTs in humans is largely extrahepatic, whereas SULT expression in rodents is predominantly hepatic. Based on microarray analysis of 79 human tissues, mRNA encoding most SULT enzymes was detected in the liver but in no case did the liver have the highest levels of an individual SULT mRNA (Chen et al., 2015a). Additionally, humans express four members of the SULT1A subfamily (1A1 to 1A4), whereas rodents express only one. In contrast, rats express four members of the SULT2A subfamily, whereas humans have only a single SULT2A gene (SULT2A1). Equivalents of mouse SULT3A1 and SULT5A1 are not expressed in humans (Gamage et al., 2006). There are also significant differences between other mammalian species. For instance, SULT activity is generally low in pigs but high in cats. The high SULT activity in cats offsets their low capacity to conjugate xenobiotics with glucuronic acid.

In rats, SULT activity varies considerably with sex and age. In mature rats, expression of various SULTs in the liver is greater in males than females: approximately twofold in the case of SULT1A1 and 10-fold in the case of SULT1C1. SULT1E1 is undetectable in the female rat liver and qualifies as a male-specific SULT in adult rats (Coughtrie, 2016). In contrast, various SULT2 enzymes are expressed to a greater extent in mature female rats and mice compared with their male counterparts (Coughtrie, 2016). Sex differences in the developmental expression of individual SULTs are the result of a complex interplay between gonadal, thyroidal, and pituitary hormones (particularly growth hormone), which similarly determine sex differences in CYP enzyme expression. However, compared with CYP enzymes, the SULTs are refractory or only marginally responsive to the enzyme-inducing effects of AhR and CAR activators such as 3-methylcholanthrene and phenobarbital, respectively, although one or more individual SULT2 enzymes are inducible by PXR agonists such as PCN. Likewise, SULT1A1, 2A1, or 2E1 expressed in Caco-2 cells are refractory to various PAHs, and 3-methylcholanthrene has no effect on SULT1A1 and SULT1A3 mRNA levels in primary human hepatocytes (Gamage et al., 2006). From rodent studies, it is generally held that AhR agonists have suppressive effects on SULT regulation. 2-AAF, dioxin, 3-methylcholanthrene, and β-naphthoflavone markedly suppress SULT1A1 and SULT12A activities and mRNA levels in rat livers (Gamage et al., 2006). In contrast, there is evidence that the rat liver hydroxysteroid SULTs (SULT2s) may be inducible by tamoxifen and estrogens (Gamage et al., 2006). For mouse SULT2A2, a functional nuclear response element responsive for CAR has been reported (Gamage et al., 2006). Human SULT2A1 has been reported to be regulated by FXR, PXR, VDR, and PPARα, whereas SULT1A1, 2A1, and 2A9 genes in mice are regulated by CAR (Tirona and Kim, 2005; Gamage et al., 2006). There are conflicting data regarding the influence of CAR ligands on SULT1A1 and SULT1A3. One study reports an 11-fold increase in SULT1A1 mRNA in primary human hepatocytes by the CAR ligand, CITCO, whereas another study could not reproduce these results for either SULT1A1 or SULT1A3 (Gamage et al., 2006). The glucocorticoid dexamethasone has been reported to induce both murine and human SULT2A1 through PXR and GR activation (Gamage et al., 2006). Human SULT2A1 mRNA and protein have also been reported to be induced by rifampin, vitamin D_3, phenobarbital, TCPOBOP, and the PPARα-agonist ciprofibrate (Runge-Morris and Kocarek, 2005). Recent reviews reinforce the complexity of the role of xenosensors (including FXR and LXR) in the induction and suppression of SULT enzymes, which often occurs in a species-, gender- and tissue-specific manner (Kodama and Negishi, 2013; Runge-Morris et al., 2013).

Induction of SULTs by rifampin may be clinically relevant. Rifampin (600 mg q.d.) has been reported to cause up to a 190% increase in the clearance of ethinyl estradiol (35 μg q.d.) (Barditch-Crovo et al., 1999). The interaction between ethinyl estradiol–containing oral contraceptives and antibiotics such as rifampin is often attributed to the induction of CYP3A4, which is the major CYP involved in the *oxidative* metabolism of ethinyl estradiol (e.g., Ortho-Evra® prescribing information). Several lines of evidence suggest that induction of CYP3A4 is not the predominant mechanism by which rifampin increases the clearance of ethinyl estradiol. First, Li et al. (1999) reported that treatment of primary cultures of human hepatocytes with rifampin (33.3 nM) caused up to a 3.3-fold increase in ethinyl estradiol 3-*O*-sulfate formation. Second, SULTs 1A1, 1A2, 1A3, 1E1, and 2A1 catalyze the 3-*O*-sulfonation of ethinyl estradiol with K_m values ranging from 6.7 to 4500 nM, nearer the pharmacologically relevant concentrations (Schrag et al., 2004). Finally, it is known that ethinyl estradiol is predominantly excreted in bile and urine as the 3-sulfate and, to a lesser extent, the 3-glucuronide (Li et al., 1999), which suggests that 3-sulfonation is the major pathway of ethinyl estradiol metabolism. Taken together, these data suggest that induction of SULTs can be clinically relevant at least for low-dose drugs that can be sulfonated with high affinity.

Some drugs must be converted to a sulfonate conjugate to exert their desired effect, including triamterene, cicletanine, and minoxidil (Wang and James, 2006). Sulfonation (as well as glucuronidation) converts morphine to more potent analgesics than the parent, with morphine-6-sulfate being 30 times more potent, and with morphine-6-glucuronide being 45 to 800 times more potent than morphine itself in rats (Wang and James, 2006). Similarly, several

sulfonated steroids such as pregnenolone sulfate and DHEA sulfate interact directly with neurotransmitter receptors. It has been found that pregnenolone sulfate and DHEA sulfate enhance memory in mice. Prevention of hydrolysis of these sulfates by the steroid sulfatase inhibitor (*para*-*O*-sulfamoyl)-*N*-tetradecanoyl tyramine increases the memory enhancement caused by DHEA sulfate in rats, which suggests there is an important role of these sulfates in the central nervous system (Wang and James, 2006). Other examples of pharmacologically active sulfonated drugs and endogenous compounds have been reported (Chen et al., 2015a).

Methylation

Methylation is a common but generally minor pathway of xenobiotic biotransformation. It differs from most other conjugation reactions by causing only modest changes in log *P* and TPSA, as shown in Table 6-3, which can decrease, rather than increase, the aqueous solubility of xenobiotics. One exception to this rule is the *N*-methylation of pyridine-containing xenobiotics, such as nicotine, which produces quaternary ammonium ions that are water-soluble and readily excreted. Another exception is the *S*-methylation of thioethers to form positively charged sulfonium ions, a reaction catalyzed by thioether methyltransferase (TEMT), which has only been identified in mice (Weinshilboum et al., 1999). Methylation masks functional groups (–OH, –SH, and –NH_2) that might otherwise be metabolized by other conjugating enzymes, which raises the question: Why did methylation evolve as a pathway of xenobiotic biotransformation? In the preceding section "Sulfonation," conjugation of certain alcohols and phenols with sulfonic acid was identified as a mechanism of activation of certain xenobiotics (e.g., those shown in Fig. 6-64). In contrast, methylation is not a mechanism of xenobiotic activation with the possible exception of arsenic (discussed later in the section). Furthermore, in the case of catechols, which are redox active and can nonenzymatically generate reactive oxygen species, methylation represents an important pathway of detoxication.

The cofactor for methylation is *S*-adenosylmethionine (SAM), the structure of which is shown in Fig. 6-57. The methyl group bound to the sulfonium ion in SAM has the characteristics of a carbonium ion and is transferred to xenobiotics and endogenous substrates by nucleophilic attack from an electron-rich heteroatom (*O*, *N*, or *S*). Consequently, the functional groups involved in methylation reactions are phenols, catechols, aliphatic and aromatic amines, *N*-heterocyclics, and sulfhydryl-containing compounds. The conversion of benzo[*a*]pyrene (B[*a*]P) to 6-methylbenzo[*a*]pyrene is a rare example of *C*-methylation. Another reaction that appears to involve *C*-methylation, the conversion of cocaine to ethylcocaine, is actually a transesterification reaction catalyzed by CES1, as shown in Fig. 6-9. Metals can also be methylated. Both inorganic mercury and arsenic can be dimethylated, and inorganic selenium can be trimethylated. The selenium atom in ebselen is methylated following the ring opening of this anti-inflammatory drug. Some examples of xenobiotics and endogenous substrates that undergo *O*-, *N*-, or *S*-methylation are shown in Fig. 6-65. During

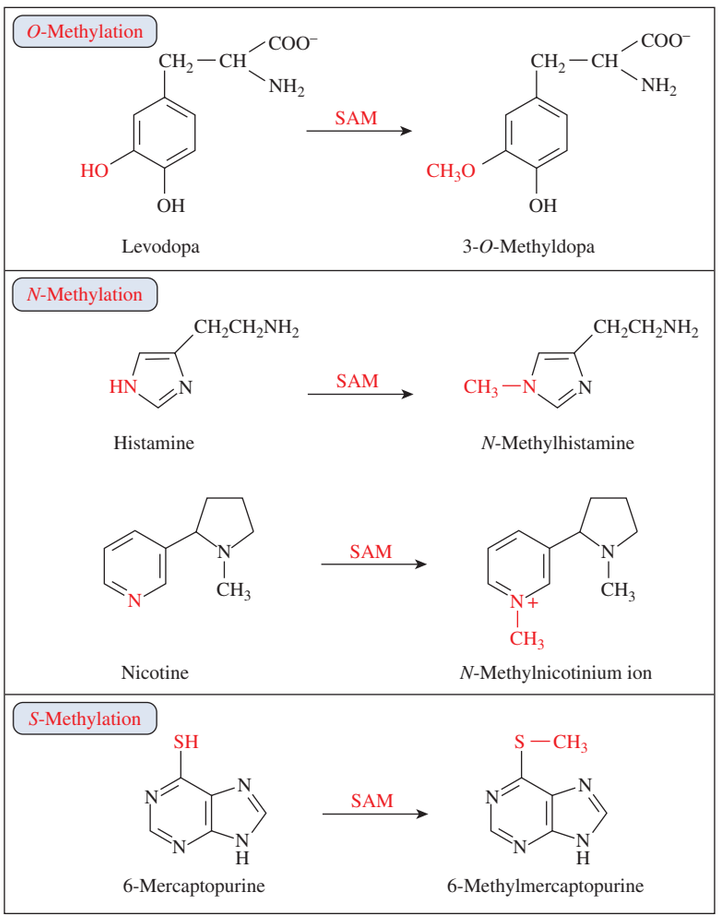

Figure 6-65. *Examples of compounds that undergo O-, N-, or S-methylation.*

these methylation reactions, SAM is converted to *S*-adenosyl-L-homocysteine (SAH). This section will cover the following methyltransferases: arsenic (III) methyltransferase (AS3MT), catechol-*O*-methyltransferase (COMT), glycine *N*-methyltransferase (GNMT), histamine *N*-methyltransferase (HNMT), indolethylamine *N*-methyltransferase (INMT), nicotinamide *N*-methyltransferase (NNMT), phenylethanolamine *N*-methyltransferase (PNMT), phenol *O*-methyltransferase (POMT) (thiol methyltransferase [TMT]), TEMT, and thiopurine methyltransferase (TPMT). Other methyltransferases that have been implicated as drug-metabolizing enzymes include guanidinoacetate *N*-methyltransferase (GAMT) and phosphatidylethanolamine *N*-methyltransferase (PEMT) (Nishimura and Naito, 2006).

The *O*-methylation of phenols and catechols is catalyzed by two different enzymes known as COMT and the enzyme historically termed POMT (Weinshilboum, 1989, 1992b). POMT is a microsomal enzyme that methylates phenols but not catechols, and COMT is both a cytosolic and microsomal enzyme with the converse substrate specificity, that is, an absolute requirement for catechol substrates (Weinshilboum, 2006). COMT plays a greater role in the biotransformation of catechols than POMT plays in the biotransformation of phenols. It should be noted that there is strong evidence to suggest that the membrane-bound POMT is the same enzyme as TMT (Weinshilboum, 2006). COMT was originally described as a cytosolic, Mg^{2+}-requiring, monomeric enzyme (M_r 25,000). However, in rats and humans, the enzyme is encoded by the COMT gene (on chromosome 22 in humans) with two different promoters and transcription initiation sites. Transcription at one site produces a cytosolic form of COMT, whereas transcription from the other site produces a membrane-bound form by adding 50 hydrophobic amino acids to the N-terminus of the microsomal COMT, which targets this form to the endoplasmic reticulum (Weinshilboum et al., 1999; Weinshilboum, 2006). The microsomal COMT is expressed at high levels in the brain and lymphocytes (Weinshilboum, 2006). The cytosolic form of COMT is present in virtually all tissues, including erythrocytes, but the highest concentrations are found in the liver and kidney. The membrane-bound form is more highly expressed in brain.

Substrates for COMT include several catecholamine neurotransmitters, such as epinephrine, norepinephrine, and dopamine; and catechol drugs, such as the anti-Parkinson disease agent levodopa (L-3,4-dihydroxyphenylalanine) and the antihypertensive drug methyldopa (α-methyl-3,4-dihydroxyphenylalanine). Catechol estrogens, which are formed by 2- or 4-hydroxylation of the steroid A-ring, are substrates for COMT, as are drugs that are converted to catechols by two consecutive hydroxylation reactions (as in the case of phenobarbital, duloxetine, and diclofenac), by ring opening of a phenyl methylenedioxy (benzodioxole) group (as in the case of stiripentol and 3,4-methylenedioxymethamphetamine), or by hydrolysis of vicinal esters (as in the case of ibopamine). Formation of catechol estrogens, particularly 4-hydroxyestradiol, has been suggested to play an important role in estrogen-induced tumor formation in hamster kidney, rat pituitary, and mouse uterus (Zhu and Liehr, 1993) (see the section "CYP1B1"). These tissues contain high levels of epinephrine or dopamine, which inhibit the *O*-methylation of 4-hydroxyestradiol by COMT. Nontarget tissues do not contain high levels of catecholamines, which suggests that 4-hydroxyestradiol induces tumor formation in those tissues that fail to methylate and detoxify this catechol estrogen. These observations in animals are especially intriguing in view of subsequent epidemiological evidence demonstrating that low COMT activity appears to increase the risk of breast cancer, with odds ratios ranging from 1.7 to 3.0 (Weinshilboum, 2006).

In the 1970s, when COMT levels in erythrocytes (predominantly the cytosolic form) were measured in human subjects, it was apparent that there was a subpopulation that displayed low levels of this enzyme. Segregation analysis indicated that erythrocyte COMT activity was an autosomal codominant trait, and that erythrocyte levels correlated with relative COMT levels in liver and lymphocyte cytosol (Weinshilboum, 2006). It was subsequently found that COMT is encoded by a single gene with alleles for a low-activity form ($COMT^L$) and high-activity form ($COMT^H$) (Weinshilboum, 1989, 1992b, 2006; Weinshilboum et al., 1999). This polymorphism results from a single G → A transition in exon 4 that results in the substitution Val_{108}Met in cytosolic COMT and Val_{158}Met in microsomal COMT (Weinshilboum et al., 1999; Weinshilboum, 2006). The presence of methionine at position 108 in the cytosolic enzyme not only decreases the catalytic activity of COMT but also decreases the thermal stability of the enzyme, which has long been used to differentiate $COMT^L$ (thermolabile) from $COMT^H$ (thermostable). In Caucasians, these allelic variants are expressed with roughly equal frequency, so that 25% to 30% of the population is homozygous for Met/Met, the low activity COMT, 20% to 25% is homozygous for Val/Val, the high activity COMT, and 50% is heterozygous (Met/Val) and has intermediate COMT activity. The Val/Val form of COMT is three- to fourfold more active than the Met/Met form of COMT. COMT activity is generally higher in Asians and African Americans due to a higher frequency of $COMT^H$ (the Val allele) (about 75% for Asians and African Americans compared with about 50% for Caucasians) (McLeod et al., 1994). Subsequent resequencing of the COMT gene has revealed numerous SNPs, with at least eight that occur with a frequency of more than 10% in Caucasians, and 11 such SNPs in African Americans. Several of these SNPs are found in the intronic regions. A list of COMT alleles can be found at http://alfred.med.yale.edu/alfred/index.asp.

The genetically determined levels of COMT in erythrocytes correlate with individual differences in the proportion of levodopa converted to 3-*O*-methyldopa and the proportion of methyldopa converted to its 3-*O*-methyl metabolite. *O*-Methylation is normally a minor pathway of levodopa biotransformation, but 3-*O*-methyldopa is the major metabolite when levodopa is administered with a dopa decarboxylase inhibitor, such as carbidopa or benserazide, which is a common clinical practice. High COMT activity, resulting in extensive *O*-methylation of levodopa to 3-*O*-methyldopa, has been associated with poor therapeutic management of Parkinson disease and an increased incidence of drug-induced toxicity (dyskinesia). A large number of epidemiological studies have been performed to examine the effects of the COMT $Val_{108/158}$Met polymorphism, and there is no evidence that the genetic polymorphism in COMT represents a risk modifier for the development of Parkinson disease (Weinshilboum et al., 1999). Talcopone, entacapone, and opicapone are drugs that inhibit COMT and are used (together with inhibitors of dopa decarboxylase) to slow the metabolism and lower the dose of levodopa in Parkinson patients (Muller, 2015). All three COMT inhibitors are nitrocatechols (catechols with an adjacent nitro group).

Egan et al. (2001) reported that COMT genotype is related in an allele-dosage manner to cognitive performance, with Met/Met individuals ($COMT^L$ phenotype) demonstrating increased executive cognition, as measured by the Wisconsin Card Sorting Test. The impact of the low-activity COMT allele was attributed to decreased dopamine catabolism in the prefrontal cortex, which results in enhanced neuronal function. Conversely, those individuals who are homozygous for Val_{108} ($COMT^H$ phenotype) appear to have decreased executive cognition, and may be at a slightly increased risk of developing schizophrenia (Egan et al., 2001). Modafinil, a

drug approved for the treatment of narcolepsy and other sleep disorders, allows better executive function performance and better vigilance throughout sleep deprivation in individuals with high COMT activity (the Val/Val allelic variant). Due to their higher brain levels of dopamine, individuals with low COMT activity (the Met/Met allelic variant) respond to lower doses of modafinil than individuals with intermediate (Val/Met) or high (Val/Val) COMT activity (Dauvilliers et al., 2015).

Several *N*-methyltransferases have been described in humans and other mammals, including PNMT, which catalyzes the *N*-methylation of the neurotransmitter norepinephrine to form epinephrine; HNMT, which specifically methylates the imidazole ring of histamine and closely related compounds (Fig. 6-65); and NNMT, which methylates compounds containing a pyridine ring, such as nicotinamide, or an indole ring, such as tryptophan and serotonin (Weinshilboum, 1989, 1992b; Weinshilboum et al., 1999). PNMT is a cytosolic enzyme expressed at high levels in adrenal medullary chromafin cells, and in neurons of the medulla oblongata, hypothalamus, as well as in sensory nuclei of the vagus nerve and the retina, and is not thought to play a significant role in the biotransformation of xenobiotics (Ji et al., 2005; Testa and Krämer, 2008, 2010).

HNMT is a cytosolic enzyme (M_r 33,000) that is highly expressed in kidney, liver, colon, prostate, ovary, and spinal cord cells (Horton et al., 2005). Its activity (which can be measured in erythrocytes) varies sixfold among individuals due to a genetic polymorphism (C → T) that results in a point mutation, namely, $Thr_{115}Ile$. The latter allele (Ile_{115}) is quite common in Caucasians and Han Chinese (10% frequency) and encodes a variant of HNMT with decreased catalytic activity and thermal stability. HNMT may influence efficacy of some drugs by a mechanism that is not yet fully understood. For instance, individuals who are heterozygous for the Ile_{115} allele have been found to exhibit significantly decreased methylprednisolone-induced cortisol suppression relative to (Thr_{115})-homozygous individuals (Hon et al., 2006). Several other polymorphisms in the noncoding region of the HNMT gene have also been identified. HNMT can be inhibited by several antihistamines, quinacrine, amodiaquine, metoprine, and tacrine (Horton et al., 2005).

NNMT is a monomeric, cytosolic enzyme (M_r ~30,000) that appears to be a member of a family of methyltransferases that includes PNMT and TEMT (the thioether *S*-methyltransferase present in mouse lung). It catalyzes the *N*-methylation of nicotinamide and structurally related pyridine compounds (including pyridine itself) to form positively charged pyridinium ions. Nicotinic acid (niacin), a commonly used lipid-lowering agent, is converted to nicotinamide in vivo, which is then methylated by NNMT (or it is incorporated into nicotinamide adenine dinucleotide [NAD]). In contrast to many other methyltransferases, NNMT is not expressed in erythrocytes.

NNMT activity in the human liver, like HNMT activity in erythrocytes, varies considerably from one individual to the next, and has a trimodal distribution dependent on variations in mRNA and protein levels, and up to 25% of the general population has high NNMT levels (Souto et al., 2005; Williams et al., 2005). It is not known to what extent genetic polymorphisms account for this variation. However, 10 SNPs in the untranslated regions of the gene have been detected in a Spanish population (Souto et al., 2005). A genome-wide scan for genes associated with plasma homocysteine levels determined that there was a statistically significant association with the NNMT gene, and, moreover, that 1 SNP (dbSNP ID#: rs694539) has a greater statistically significant association with homocysteine levels ($P = .017$) (Souto et al., 2005). Homocysteine plasma levels are an independent intermediate risk marker for osteoporotic fractures, congestive heart failure, venous thrombosis, myocardial infarction, stroke, and Alzheimer disease (Souto et al., 2005). In humans, the only source of homocysteine is from the demethylation of methionine in a multistep pathway that involves SAM-dependent methyltransferases to form *S*-adenosylhomocysteine, the immediate precursor to homocysteine. Taken together, these data suggest that high methyltransferase activity could contribute to hyperhomocysteinemia. Of the many SAM-dependent methyltransferase genes examined for an association with homocysteine levels, only NNMT (which is highly expressed in the liver) was found to show a significant association (Souto et al., 2005). NNMT is reported to be expressed in the brain and has been implicated as a component of the etiology of idiopathic Parkinson disease because it can convert 4-phenylpyridine to MPP^+, which is known to cause Parkinson disease symptoms due to its toxic effect on neuronal mitochondria (see the section "Amine Oxidases" and Fig. 6-33) (Williams et al., 2005).

There are numerous other human *N*-methyltransferases (as well as *O*-, *S*-, and *C*-methyltransferases) that appear to play relatively specific roles in the methylation of endogenous compounds, and most have not been well characterized with regard to their capability to methylate xenobiotics (there are at least 39 SAM-dependent methyltransferases in humans) (Souto et al., 2005). For instance, INMT catalyzes the *N*-methylation of tryptamine and structurally related compounds (Thompson et al., 1999). Other such enzymes that were initially thought to play a role only in the *N*-methylation of endogenous compounds were later found to play a role, albeit a minor one, in the *N*-methylation of one or more xenobiotics. Amine *N*-methyltransferase (AMNT, also called arylamine *N*-methyltransferase or nicotine *N*-methyltransferase), which is highly expressed in the human thyroid and is also found in the adrenal gland and lung, exhibits some activity toward tryptamine and has been also found to preferentially methylate the pyridine nitrogen of *R*-nicotine, which gives rise to nicotine isomethonium ions (Hukkanen et al., 2005). GNMT is thought to play an important role in the regulation of methyl group metabolism in the liver and pancreas through regulation of the ratio between *S*-adenosyl-L-methionine and SAH. Rat data show that the tetrameric form of the GNMT has catalytic activity, and the dimeric form binds PAHs. There is also evidence that the dimeric form of human GNMT sequesters B[*a*]P, and thereby decreases its cytotoxic effects (Chen et al., 2004b; Lee et al., 2006).

The system that is used to classify human *N*-methyltransferases may not be appropriate for other species. In guinea pigs, for example, both nicotine and histamine are methylated by a common *N*-methyltransferase. Guinea pigs have an unusually high capacity to methylate histamine and xenobiotics. The major route of nicotine biotransformation in the guinea pig is methylation, although *R*-nicotine is preferentially methylated over its *S*-enantiomer (Cundy et al., 1985). Guinea pigs also methylate the imidazole ring of cimetidine.

S-Methylation is an important pathway in the biotransformation of sulfhydryl-containing xenobiotics, such as the antihypertensive drug captopril, the antirheumatic agent D-penicillamine, the antineoplastic and immunosuppressive drugs 6-mercaptopurine, 6-thioguanine, and azathioprine, metabolites of the alcohol deterrent disulfiram, and the deacetylated metabolite of the antidiuretic, spironolactone. In humans, *S*-methylation is catalyzed by at least two enzymes TPMT and TMT (which may be the same enzyme as POMT).

TPMT is a cytoplasmic enzyme that preferentially methylates aromatic and heterocyclic compounds such as the thiopurine

drugs 6-mercaptopurine, 6-thioguanine, and azathioprine. TMT is a microsomal enzyme that preferentially methylates aliphatic sulfhydryl compounds such as captopril, D-penicillamine, and disulfiram derivatives. It has also been found to methylate the heterocyclic thiol-containing leaving groups of some cephalosporins (Wood et al., 2002), the thiazolidinedione drug, MK-0767, a dual α/γ PPAR agonist (Karanam et al., 2004), dithiothreitol (Weinshilboum, 2006), and some thiofuran flavoring agents (Lake et al., 2003). Although a gene that encodes TMT has not yet been definitively identified, there is strong evidence to suggest that the membrane-bound POMT is the same enzyme as TMT, which means that TMT could also catalyze the *O*-methylation of phenols (Weinshilboum, 2006).

Both TMT and TPMT are present in erythrocytes at levels that reflect the expression of TPMT and TMT in liver and other tissues. Although TPMT and TMT are independently regulated, their expression in erythrocytes is largely determined by genetic factors. TPMT is encoded by a single gene with alleles for a low-activity form ($TPMT^L$) and for a high-activity form ($TPMT^H$). The allele frequencies of $TPMT^L$ and $TPMT^H$ are 0.06 and 0.94, respectively, which produces a trimodal distribution of TPMT activity with low, intermediate, and high activity expressed in 0.3%, 11.1%, and 88.6% of Caucasians, respectively. At least 28 separate genetic polymorphisms have been identified and most are associated with low TPMT activity, with the *2, *3A, *3B, and *3C alleles accounting for 80% to 95% of the $TPMT^L$ phenotype (Weinshilboum, 2006; Ujiie et al., 2008; Wang et al., 2010a; Asadov et al., 2017; Liu et al., 2017a; Tamm et al., 2017). In Caucasians, the allele that is most commonly associated with the $TPMT^L$ phenotype is TPMT*3A (5%), which contains two nonsynonymous SNPs: $Ala_{154}Thr$ and $Tyr_{240}Cys$ (Wood et al., 2006). These amino acid changes (and those in the TPMT*3B and TPMT*3C variants) lead to aggregation and rapid degradation of expressed TPMT by a ubiquitin/proteasome-dependent mechanism (Wang et al., 2005). Another variant TPMT*4 results in alternative TPMT mRNA splicing and reduced enzyme expression, leading to low TPMT activity in individuals carrying this allele (Wang et al., 2010a).

Thiopurine drugs such as 6-mercaptopurine and its prodrug azathioprine are widely used in the treatment of cancer, such as acute lymphoblastic leukemia, inflammatory disorders, such as inflammatory bowel disease, and autoimmune diseases, such as rheumatoid arthritis, systemic lupus erythromatosus, autoimmune hepatitis, and generalized eczematous disorders. Patients with low TPMT activity are at increased risk of thiopruine toxicity, which includes myelosuppression (bone marrow toxicity), gastrointestinal disturbances (nausea and vomiting), hepatotoxicity, and pancreatitis, which can lead to discontinuation of treatment with 6-merceptopurine or azathioprine in up to one-third of patients (Weinshilboum, 1989, 1992b; Liu et al., 2015b; Abaji and Krajinovic, 2017; Asadov et al., 2017). The thiopurine drugs metabolized by TPMT have a relatively narrow therapeutic index. They are metabolized by xanthine oxidoreductase (in addition to TPMT), but because xanthine oxidoreductase is not present in hematopoietic tissues, TPMT activity in these tissues is more important in the avoidance of life-threatening myelosuppression at standard doses (Weinshilboum, 2006). Phenotyping for the TPMT genetic polymorphism represents one of the first examples in which testing for a genetic variant has entered standard clinical practice (Weinshilboum et al., 1999; Liu et al., 2015b; Abaji and Krajinovic, 2017; Asadov et al., 2017). The clinical relevance of TPMT polymorphisms is reflected by the inclusion of TPMT as a "valid biomarker" for pharmacogenomics, along with CYP2D6 polymorphisms, in the FDA's 2005 "Guidance for Pharmacogenomic Data Submission." TPMT can be inhibited by benzoic acid derivatives, which also complicates therapy with drugs that are metabolized by TPMT. Patients with inflammatory bowel disorders such as Crohn disease are often treated with thiopurine drugs, which are metabolized by TPMT, and with sulfasalazine or olsalazine, which are potent TPMT inhibitors. The combination of these drugs can lead to thiopurine-induced myelosuppression.

A genetic polymorphism for TMT also has been described, but its pharmacological and toxicological significance remains to be determined. The molecular basis for the polymorphism has not been determined, but studies have shown that 98% of the fivefold individual variation in erythrocyte TMT activity is due to inheritance, with an allele for high TMT activity having a frequency of 12%. TMT is relatively specific for aliphatic sulfhydryl compounds such as 2-mercatoethanol, captopril, D-penicillamine, and *N*-acetylcysteine. It also rapidly methylates a dihydro metabolite of ziprasidone that is formed by aldehyde oxidase, as shown in Fig. 6-7 (Obach et al., 2005). TMT is present at high levels in the colonic mucosa and is also expressed in liver microsomes and erythrocyte membranes. It is not inhibited by benzoic acid derivatives, but it is inhibited by the CYP inhibitor proadifen (aka SKF-525A) (Weinshilboum et al., 1999).

As shown in Fig. 6-55, clopidogrel is a prodrug that is converted to its active metabolite, a ring-opened thiol, by sequential CYP- and GSH-dependent steps. The active metabolite, H4, is one of four diastereomers formed during this process. Due to stereopreferential metabolism by CYP enzymes, clopidogrel is converted to H3, an inactive metabolite, to a greater extent (about threefold) than H4 but the circulating levels of H3 and H4 are roughly the same. This is because microsomal TMT preferentially methylates H3 over H4 by almost 100-fold (Liu et al., 2015a).

Some of the hydrogen sulfide produced by anaerobic bacteria in the intestinal tract is converted by *S*-methyltransferases to methane thiol and then to dimethylsulfide. Another source of substrates for *S*-methyltransferases are the thioethers of GSH conjugates. GSH conjugates are hydrolyzed to cysteine conjugates, which can either be acetylated to form mercapturic acids or cleaved by cysteine-conjugate β-lyase (CCBL1). This β-lyase pathway converts the cysteine conjugate to pyruvate, ammonia, and a sulfhydryl-containing xenobiotic, which is a potential substrate for *S*-methylation.

Methylation can also lead to increased toxicity. AS3MT is a methyltransferase (previously called Cyt19) that methylates inorganic arsenic to form methylarsonic and dimethylarsonic acids, which are more cytotoxic and genotoxic than arsenate and arsenite (Wood et al., 2006). As many as 27 polymorphisms have been identified in this gene, with two rare alleles that cause markedly decreased activity and immunoreactive protein levels, and one frequent allele (i.e., about 10% in both African Americans and Caucasians) that causes increased activity and immunoreactive protein levels (Wood et al., 2006). Up to 1% of African Americans and Caucasians would be expected to be homozygous for the allele that encodes the high-activity AS3MT, and this may potentially lead to increased arsenic toxicity in such individuals. Contrary to expectation, AS3MT knockout mice are more susceptible, not less susceptible, than wild-type mice to the toxicity of arsenite (such as urinary bladder hyperplasia) (Antonelli et al., 2014). It is possible that methylation of inorganic arsenic by AS3MT represents a detoxication process in mice and an activation process in humans.

Acetylation

N-Acetylation is a major route of biotransformation for xenobiotics containing an aromatic amine (phenyl-NH_2) or a hydrazine group (R–NH–NH_2), which are converted to aromatic amides (phenyl-NH–$COCH_3$) and hydrazides (R–NH–NH–$COCH_3$), respectively

(Evans, 1992). *N*-Acetylation of aromatic amines and hydrazines occurs on nitrogen atoms with a low $pK_a(B)$, usually less than 5. Xenobiotics containing primary aliphatic amines, most of which have $pK_a(B)$ values greater than 8, are rarely substrates for *N*-acetylation. Notable exceptions are the antibacterial agent trovafloxacin, the primary metabolite of the β-adrenoreceptor blocker propranolol, and cysteine conjugates, which are formed from GSH conjugates and converted to mercapturic acids by *N*-acetylation in the kidney (see the section "Glutathione Conjugation") (Testa and Krämer, 2008, 2010). *N*-acetylation of aliphatic amines lowers their $pK_a(B)$ value from above 8 to below 6, which lowers their ion-partitioning into lysosomes and reduces their volume of distribution, as described in the section "Introduction." In a few cases, the *N*-acetylation of aliphatic acidic amines (such as the amine in a sulfonamide, which is present as an anion, not a cation) has also been documented, an example of which is *N*-acetylation of the anticonvulsant drug zonisamide (Testa and Krämer, 2008, 2010). Like methylation, *N*-acetylation has a negligible effect on log *P* and TPSA, as shown in Table 6-3; hence, *N*-acetylation has a negligible effect on aqueous solubility and does little to promote the renal and biliary excretion of xenobiotics.

The *N*-acetylation of xenobiotics is catalyzed by *N*-acetyltransferases (NATs) and requires the cofactor acetyl coenzyme A (acetyl-CoA), the structure of which is shown in Fig. 6-57. The reaction occurs in two sequential steps according to a *ping-pong Bi–Bi* mechanism (Hein, 1988). In the first step, the acetyl group from acetyl-CoA is transferred to a cysteine residue in the NAT active site with release of CoA ($E–SH + CoA–SCOCH_3 \rightarrow E–S–COCH_3 + CoA–SH$). In the second step, the acetyl group is transferred from the acylated enzyme to the amino group of the substrate with regeneration of the enzyme. For "strongly" basic amines ($pK_a(B) > 8$), the rate of *N*-acetylation is determined by the first step (acetylation of the enzyme), whereas the rate of *N*-acetylation of "weakly" basic amines ($pK_a(B) < 6$) is determined by the second step (transfer of the acetyl group from the acylated enzyme to the acceptor amine). In certain cases (discussed later in this section), NATs can catalyze the *O*-acetylation of hydroxylamines.

NATs are cytosolic enzymes found in the liver and many other tissues of most mammalian species, with the notable exception of the dog, fox, and musk shrew (*Suncus marinus*) which are unable to acetylate xenobiotics (a notable exception being the ability of dogs to *N*-acetylate cyanamide, which contains an acidic amine group) (Nakura et al., 1995; Trepanier et al., 1997; Sim et al., 2008; Testa and Krämer, 2008, 2010). In contrast to other xenobiotic-biotransforming enzymes, the number of NATs known to play a role in xenobiotic metabolism is limited (Vatsis et al., 1995; Boukouvala and Fakis, 2005). Rabbits and hamsters express only two NAT enzymes, known as NAT1 and NAT2, whereas mice and rats express three enzymes, namely, NAT1, NAT2, and NAT3. The two xenobiotic-acetylating human enzymes are NAT1 and NAT2, which are encoded by two highly polymorphic genes located on chromosome 8. Other human NAT genes are NAT6, NAT8 to NAT10, NAT14, and NAT16, located on other chromosomes. The activities and expression pattern of these enzymes have not yet been definitively characterized, although some of these genes have been associated with atopic dermatitis or psoriasis (NAT9) and nasopharyngeal cancer (NAT6) (Helms et al., 2003; Bowcock and Cookson, 2004; Duh et al., 2004; Yamada and Ymamoto, 2005; Morar et al., 2006). Individual NATs and their allelic variants were named in the order of their description in the literature, which makes for a somewhat confusing nomenclature system (Vatsis et al., 1995). For example, in humans, the "wild-type" NAT1 and NAT2 alleles are designated NAT1*4 and NAT2*4 (Hein, 2006; McDonagh et al., 2014). Information on allelic variants of NATs is available at http://nat.mbg.duth.gr/.

In each species examined, NAT1 and NAT2 are closely related proteins (79% to 95% identical in amino acid sequence) with an active-site cysteine residue (Cys_{68}) in the N-terminal region (Grant et al., 1992; Vatsis et al., 1995). In addition to the active-site cysteine residue, the presence of a histidine residue (His_{107}) and an aspartate residue (Asp_{122}) are required for activity, forming a catalytic triad necessary for the transfer of an acetyl group from acetyl-CoA to the substrate (Sandy et al., 2005; Sim et al., 2008). Human NAT1 and NAT2 genes are composed of intronless open reading frames of 870 bp on the same chromosome with a NAT pseudogene (NATP1) between them, and encode proteins of 290 amino acids that share 87% homology in the coding region (Boukouvala and Fakis, 2005; Hein, 2006).

Despite their proximity on the same chromosome, NAT1 and NAT2 are independently regulated proteins. For instance, human NAT1 protein and/or mRNA have been detected in every tissue examined (e.g., liver, gastrointestinal tract, leukocytes, erythrocytes, bladder, uroepithelial cells, mammary, lung, placenta, kidney, pineal gland, skeletal muscle, heart, brain, and pancreas) and are present from the blastocyst stage, whereas NAT2 is mainly expressed in the liver, small intestine, and codon. However, most (but not all) of the tissues that express NAT1 also express low levels of NAT2 mRNA (Debiec-Rychter et al., 1999).

NAT1 and NAT2 have different but overlapping substrate specificities, although no substrate is exclusively *N*-acetylated by one enzyme or the other. Substrates preferentially *N*-acetylated by human NAT1 include 4-aminobenzoic acid (PABA), 4-aminosalicylic acid, sulfamethoxazole, and sulfanilamide, whereas substrates preferentially *N*-acetylated by human NAT2 include isoniazid, hydralazine, procainamide, dapsone, aminoglutethimide, and sulfamethazine. Some investigators have used PABA as a selective probe/index substrate for wild-type NAT1, and either sulfamethazine or sulfadiazine as selective probe/index substrate for wild-type NAT2 (Winter and Unadkat, 2005). Some xenobiotics, such as the carcinogenic aromatic amine, 2-aminofluorene (2-AF), are *N*-acetylated equally well by NAT1 and NAT2. The calcium-sensitizing agent levosimendan, developed for the treatment of congestive heart failure, has a pharmacologically active *N*-acetylated metabolite produced by NAT2 (Testa and Krämer, 2008, 2010). Other drugs that are substrates for either NAT1 or NAT2 include acebutolol, amantadine, amonafide, amrinone, benzocaine, declopramide, metamizole, and phenelzine (Gonzalez and Tukey, 2006; Sirot et al., 2006; Sim et al., 2008).

Several drugs are *N*-acetylated following their biotransformation by hydrolysis, reduction, or oxidation. For example, caffeine is N_3-demethylated by CYP1A2 to paraxanthine (Fig. 6-50), which is then *N*-demethylated to 1-methylxanthine and *N*-acetylated to 5-acetylamino-6-formylamino-3-methyluracil (AFMU) by NAT2. The ratio of AFMU to 1-methylxanthine can be used to determine acetylator phenotype (Testa and Krämer, 2008, 2010). Other drugs converted to metabolites that are *N*-acetylated by NAT2 include sulfasalazine, nitrazepam, and clonazepam. Examples of drugs that are *N*-acetylated by NAT1 and NAT2 are shown in Fig. 6-66. It should be noted, however, that there are species differences in the substrate specificity of NATs. For example, PABA is preferentially *N*-acetylated by NAT1 in humans and rabbits but by NAT2 in mice and hamsters.

Genetic polymorphisms for *N*-acetylation have been documented in humans, hamsters, rabbits, and mice (Evans, 1992; Vatsis et al., 1995; Hirvonen, 1999; Hein et al., 2000; Sim et al., 2008). The impact of genetic polymorphisms of human NATs on drug

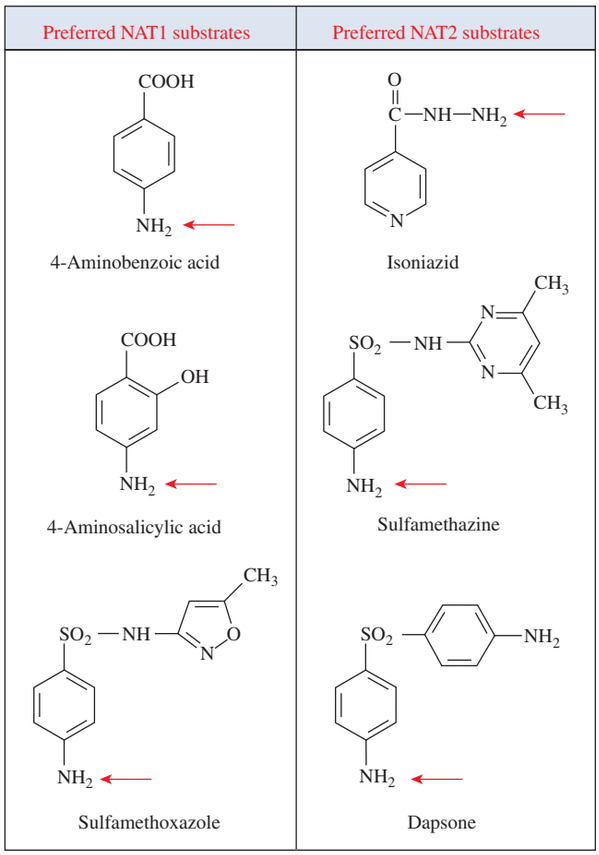

Figure 6-66. *Examples of substrates for the human N-acetyltransferases, NAT1, and the highly polymorphic NAT2.*

toxicity and environmental carcinogenesis, such as the incidence of cancer associated with cigarette smoking and the consumption of cooked meat, has attracted considerable attention. However, the literature is replete with contradictory findings (McDonagh et al., 2014). A further complication is that some genetic polymorphisms affect the *N*-acetylation of compounds in a substrate-dependent manner (McDonagh et al., 2014). NAT1 and NAT2 used to be referred to as *monomorphic* and *polymorphic* NATs because only the latter enzyme was thought to be genetically polymorphic. However, at least 28 allelic variants have now been documented for the human NAT1 gene, compared with 88 for NAT2 (McDonagh et al., 2014). In general, NAT1 allelic variants are less prevalent than NAT2 allelic variants; hence, there is less genetically determined variation in the metabolism of "NAT1 substrates."

A series of clinical observations in the 1950s established the existence of *slow* and *fast acetylators* of the antitubercular drug isoniazid, which is now known to be primarily acetylated by NAT2. In general, about 50% of patients treated with isoniazid have adverse events such as peripheral neuropathy and hepatotoxicity. These adverse effects are more pronounced in NAT2 slow acetylators, although some early reports suggested fast acetylators were at increased risk of isoniazid-induced liver injury (discussed later in this section). NAT2 slow acetylators also exhibit a higher incidence of adverse events with clonazepam, hydralazine, procainamide, and sulfonamides, such as sulfamethoxazole and sulfasalazine (Sirot et al., 2006; McDonagh et al., 2014). The incidence of the NAT2 slow acetylator phenotype is high in Middle Eastern populations (e.g., about 92% in Egyptians), intermediate in Caucasian and African populations (e.g., about 50% to 59% in Caucasian Americans, Australians, and Europeans; about 41% in African Americans; about 50% to 60% in Africans), and low in Asian populations (e.g., ~=about 20% in Chinese; about 8% to 10% in Japanese) (Sirot et al., 2006). Many studies have demonstrated the typical bimodal distribution of fast and slow acetylators with drugs such as isoniazid, but other drugs, such as caffeine and sulfamethazine, exhibit slow, intermediate, and fast acetylator phenotypes (Hein, 2006). Parkin et al. (1997) also demonstrated that isoniazid elimination is trimodal, and that phenotype and genotype were concordant.

The NAT2 slow acetylator phenotype is caused by various single nucleotide polymorphisms in the NAT2 gene that decrease NAT2 activity, decrease enzyme stability, or target the enzyme for proteasomal degradation. At least 88 allelic variants of human NAT2 have been documented. The wild-type enzyme is NAT2*4. Allelic variants that do NOT appear to affect NAT2 activity are *11A, *12A–C, *13, and *18. Common allelic variants associated with the NAT2 poor acetylator phenotype include *5 (rs1801280), *6 (rs1799930), *7 (rs1799931), and *14 (rs1801279) (McDonagh et al., 2014). NAT2*5 is a point mutation $T_{341}C$ (which causes the amino acid substitution $Ile_{114}Thr$) that decreases V_{max} for *N*-acetylation without altering the K_m for substrate binding or the stability of NAT2. The NAT2*5 allele is the most common cause of the slow acetylator phenotype in Caucasians (e.g., frequency of about 50% in the United Kingdom) but is rarely observed in Koreans (i.e., less than 5%) (Hein, 2006). There are 10 known NAT2*5 alleles, designated NAT2*5A through NAT*5J. The alleles containing only the $Ile_{114}Thr$ substitution are NAT2*5A (which also contains a silent $C_{481}T$ nucleotide change) and NAT2*5D. The others contain this and at least one other nucleotide and/or amino acid substitution, and NAT2*5B confers the "slowest acetylator" phenotype (Patin et al., 2006). The NAT2*7 allele is more prevalent in Asians than Caucasians or Africans (Hein, 2006), and involves either a point mutation $G_{857}A$ (i.e., NAT2*7A) or both this change and $C_{282}T$ (i.e., NAT2*7B). Both of these changes cause the amino acid substitution $Gly_{286}Glu$, which decreases the stability, rather than the activity, of NAT2. NAT2*6 (more common in southern India) and NAT2*14 (present mainly in Africa and Spain) also result in one or more amino acid changes that lead to decreased NAT2 activity, whereas the amino acid change in NAT2*12 (present mainly in Africa and Spain) does not decrease activity (Hein, 2006). Within the slow NAT2 acetylator phenotype there is considerable variation in rates of xenobiotic *N*-acetylation. This is partly because different mutations in the NAT2 gene have different effects on NAT2 activity and/or enzyme stability, heterozygotes retain moderate NAT2 activity, and the *N*-acetylation of "NAT2-substrates" by NAT1 becomes significant in slow NAT2 acetylators.

The slowest acetylator haplotype, namely NAT2*5B, which has the strongest association with bladder cancer, appears to have been positively selected during the last 6500 years in western and central Eurasians, which suggests that slow acetylation conferred an evolutionary advantage within this population (Patin et al., 2006). Moreover, because most of the NAT2 polymorphisms that lead to slow acetylation are present at high frequencies in various populations, it would seem that varied rates of acetylation may be an important human adaptation to environmental variables. Because acetylation can be very important in the determination of the interaction between human populations and many xenobiotics in their particular environment (e.g., through different diets and lifestyles), it is not surprising that they are recent targets for natural selection. Today, slow acetylation can be a disadvantage inasmuch as it predisposes to the toxicity of several drugs.

At least 28 allelic variants have now been documented for the human NAT1 gene, although these variants are less prevalent than

the NAT2 allelic variants; hence, there is less genetically determined variation in the metabolism of "NAT1 substrates." Nevertheless, there is evidence that phenotypic differences in the *N*-acetylation of 4-aminosalicylic acid are distributed bimodally, consistent with the existence of low- and high-activity forms of NAT1. Furthermore, an extremely slow acetylator of 4-aminosalicylic acid has been identified with mutations in both NAT1 alleles: one that decreases NAT1 activity and stability and one that encodes a truncated and catalytically inactive form of the enzyme. Two NAT1 variants, NAT1*10 and NAT1*11, are gain-of-function polymorphisms that lead to increased efficiency of protein translation (Wang et al., 2011b). Individuals homozygous for NAT1*10 or heterozygous for NAT1*11 are classified as fast acetylators, whereas those rare individuals who are homozygous for NAT1*11 have been classified as ultrafast acetylators (Wang et al., 2011b). Both NAT*10 and NAT*11 alleles are risk modifiers of sulfamethoxazole-induced hypersensitivity in HIV/AIDS patients, such that individuals who are NAT1 *fast* acetylators but are also NAT2 *slow* acetylators are protected against this type of hypersensitivity (Wang et al., 2011b). It has also been demonstrated that NAT1*16 but not NAT1*10 or NAT1*11 causes a 50% decrease in NAT1 activity and NAT1 protein levels in COS-1 cell cytosol (Soucek et al., 2004). Cascorbi et al. (2001) found that individuals who express NAT1*10 and NAT2*4 (i.e., intermediate NAT1 activity and normal NAT2 activity) were at a significantly lower risk of bladder cancer, especially when exposed to environmental carcinogens (Cascorbi et al., 2001). It is therefore likely that the interplay between NAT1 and NAT2 phenotypes is relevant to susceptibility to certain carcinogens.

Genetic polymorphisms in NAT2 have a number of pharmacological and toxicological consequences for drugs that are *N*-acetylated by this enzyme. The pharmacological effects of the antihypertensive drug hydralazine are more pronounced in slow NAT2 acetylators. Slow NAT2 acetylators are predisposed to several drug toxicities, including nerve damage (peripheral neuropathy) from isoniazid and dapsone, systemic lupus erythematosus from hydralazine and procainamide, and the toxic effects of coadministration of the anticonvulsant phenytoin with isoniazid. Slow NAT2 acetylators who are also deficient in glucose-6-phosphate dehydrogenase are particularly prone to hemolysis from certain sulfonamides. HIV-infected individuals of the slow acetylator phenotype suffer more often from adverse drug events (ADEs) and, among patients with Stevens–Johnson syndrome, the overwhelming majority are slow acetylators. Fast NAT2 acetylators are predisposed to the myelotoxic effects of amonafide because *N*-acetylation retards the clearance of this antineoplastic drug, which is thought to be due to inhibition of CYP1A2 by *N*-acetylamonofide (McDonagh et al., 2014).

Early epidemiological studies suggested that rapid NAT2 acetylators were at increased risk for the development of isoniazid-induced liver toxicity; however, the current consensus is that slow NAT2 acetylation is a risk modifier for isoniazid-induced hepatotoxicity while rapid acetylators are protected from toxicity (Metushi et al., 2016; Wang et al., 2016a). Following its acetylation by NAT2, isoniazid can be hydrolyzed to isonicotinic acid and acetylhydrazine ($CH_3CO–NHNH_2$). The latter metabolite can be *N*-hydroxylated by FMO or CYP to a reactive intermediate, as shown in Fig. 6-43. The generation of a reactive metabolite from acetylhydrazine would seem to provide a mechanistic basis for enhanced isoniazid hepatotoxicity in fast acetylators. However, acetylhydrazine can be further acetylated to diacetylhydrazine ($CH_3CO–NHNH–COCH_3$), and this detoxication reaction is also catalyzed by NAT2. Therefore, acetylhydrazine is both produced and detoxified by NAT2; hence, slow acetylation, not fast acetylation, becomes the risk modifier for isoniazid-induced hepatotoxicity, just as it is for isoniazid-induced peripheral neuropathy. Isoniazid can also be directly hydrolyzed to yield isonicotinic acid and hydrazine ($H_2N–NH_2$). Hydrazine (also a toxic substance used as rocket propellant) has been proposed to be the hepatotoxic metabolite of isoniazid as slow acetylators have significantly higher plasma concentrations of hydrazine relative to rapid acetylators (Testa and Krämer, 2008, 2010; Metushi et al., 2011). Rifampin and alcohol have been reported to enhance the hepatotoxicity of isoniazid. These drug interactions support a growing body of evidence that isoniazid itself is converted to one or more reactive metabolites that result in covalent binding to protein (hapten formation), which in severe cases of isoniazid-induced liver injury trigger an immune response. In support of this interpretation, isoniazid hepatotoxicity is more severe in NAT2 slow acetylator who also carry the high-activity CYP2E1 c1/c1 genotype (Metushi et al., 2011). Furthermore, circulating antibodies against isoniazid-adducted proteins (antidrug antibodies) and CYP enzymes (antibodies against CYP2E1, 3A4, and 2C9) have been found in patients with severe isoniazid-induced liver injury (Metushi et al., 2014). Isoniazid is an antitubercular drug, and its inactivation by NAT2 is interesting from the perspective that several organisms, including *Mycobacterium tuberculosis*, express a NAT2-like enzyme, which has implications for isoniazid resistance in tuberculosis.

Aromatic amines can be both activated and deactivated by NATs (Kato and Yamazoe, 1994; Hirvonen, 1999; Hein et al., 2000). The NATs detoxify aromatic amines by converting them to the corresponding amides because aromatic amides are less likely than aromatic amines to be activated to DNA-reactive metabolites by CYP, peroxidases such as PHS, and UGTs (see the section "Glucuronidation and Formation of Acyl-CoA Thioesters"). However, NATs can activate aromatic amines if they are first *N*-hydroxylated by CYP because NATs can also function as *O*-acetyltransferases and convert hydroxylamines to acetoxy esters (*aryl*-NHOH → *aryl*-NH–O–$COCH_3$). As shown in Fig. 6-16, the acetoxy esters of hydroxylamines, like the corresponding sulfonate esters (Fig. 6-64), can break down to form highly reactive nitrenium and carbonium ions that bind to DNA. NATs catalyze the *O*-acetylation of *N*-hydroxyaromatic amines by two distinct mechanisms. The first reaction, which is exemplified by the conversion of *N*-hydroxyaminofluorene to *N*-acetoxyaminofluorene, requires acetyl-CoA and proceeds by the same mechanism previously described for *N*-acetylation. The second reaction is exemplified by the conversion of 2-acetylaminofluorene (2-AAF) to *N*-acetoxyaminofluorene, which does not require acetyl-CoA but involves an intramolecular transfer of the *N*-acetyl group from nitrogen to oxygen. These reactions are shown in Fig. 6-67.

Genetic polymorphisms in NAT2 have been reported to influence susceptibility to aromatic amine–induced bladder and colon cancer (see the section "Glucuronidation and Formation of Acyl-CoA Thioesters") (Evans, 1992; Kadlubar, 1994; Hirvonen, 1999; Hein et al., 2000; Sim et al., 2008; Ma et al., 2016). Bladder cancer is thought to be caused by bicyclic aromatic amines (benzidine, 2-aminonaphthalene, and 4-aminobiphenyl), whereas colon cancer is thought to be caused by heterocyclic aromatic amines, such as the products of amino acid pyrolysis (e.g., 2-amino-6-methylimidazo[4,5-*b*]pyridine or PhIP, and others listed in Table 6-18). Epidemiological studies suggest that slow NAT2 acetylators are more likely than fast NAT2 acetylators to develop bladder cancer from cigarette smoking and from occupational exposure to bicyclic aromatic amines. The possibility that slow NAT2 acetylators are at increased risk for aromatic amine–induced cancer is supported by the finding that dogs, which are poor acetylators, are highly prone to aromatic amine–induced bladder cancer. By comparison, fast NAT2

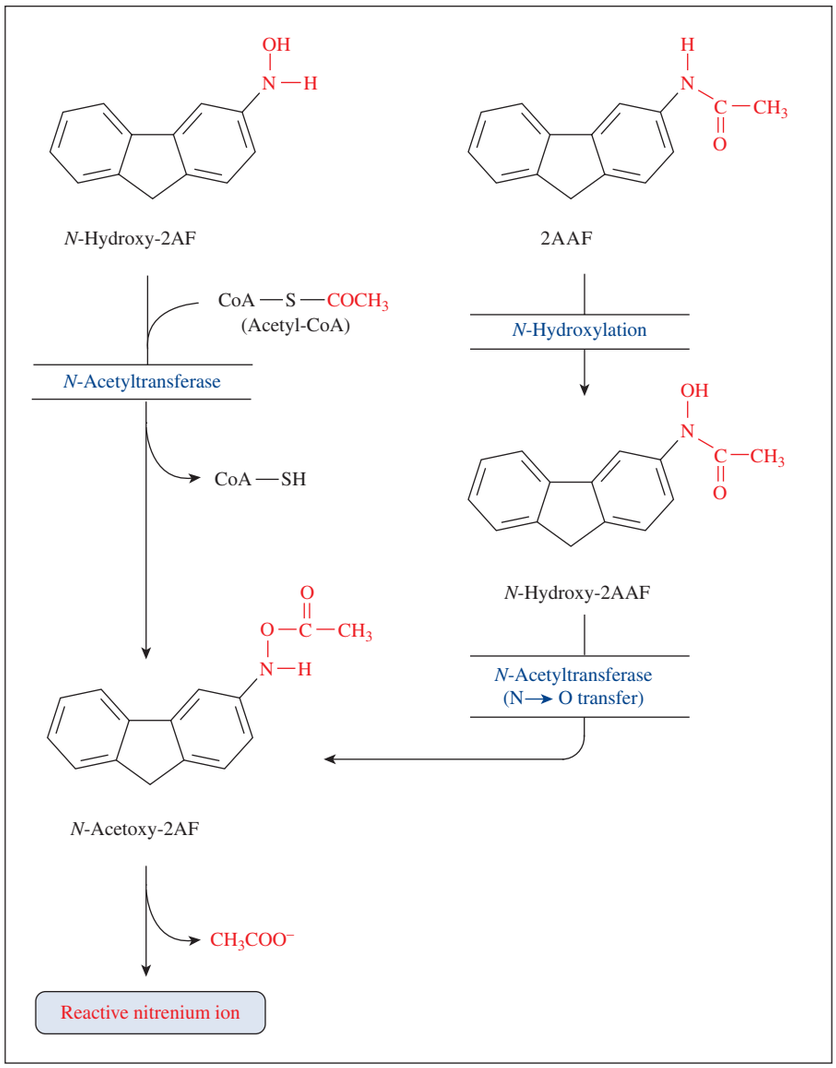

Figure 6-67. *Role of N-acetyltransferase in the O-acetylation of N-hydroxy-2-aminofluorene (N-hydroxy-2-AF) and the intramolecular rearrangement of N-hydroxy-2-acetylaminofluorene (N-hydroxy-2-AAF).*

acetylators appear to be at increased risk for colon cancer from heterocyclic aromatic amines.

The influence of acetylator phenotype on susceptibility to aromatic amine–induced cancer can be rationalized on the ability of NATs to activate and detoxify aromatic amines and by differences in the substrate specificity and tissues distribution of NAT1 and NAT2 (recall that NAT1 is expressed in virtually all tissues, whereas NAT2 is expressed mainly in the liver and gastrointestinal tract). Both NAT1 and NAT2 catalyze the *O*-acetylation (activation) of *N*-hydroxy bicyclic aromatic amines, whereas the *O*-acetylation of *N*-hydroxy heterocyclic aromatic amines is preferentially catalyzed by NAT2. Bicyclic aromatic amines can also be *N*-acetylated (detoxified) by NAT1 and NAT2, but heterocyclic aromatic amines are poor substrates for both enzymes. Therefore, the fast acetylator phenotype protects against aromatic amine–induced bladder cancer because NAT2 (as well as NAT1) catalyzes the *N*-acetylation (detoxication) of bicyclic aromatic amines in the liver. In slow acetylators, a greater proportion of the bicyclic aromatic amines are activated through *N*-hydroxylation by CYP1A2. These *N*-hydroxylated aromatic amines can be activated by *O*-acetylation, which can be catalyzed in the bladder itself by NAT1. A high level of NAT1 in the bladder is a risk modifier for aromatic amine–induced bladder cancer. In addition, the fast acetylator phenotype potentiates the colon cancer–inducing effects of heterocyclic aromatic amines. These aromatic amines are poor substrates for NAT1 and NAT2, so that high levels of NAT2 in the liver do little to prevent their *N*-hydroxylation by CYP1A2. The *N*-hydroxylated metabolites of heterocyclic aromatic amines can be activated by *O*-acetylation, which can be catalyzed in the colon itself by NAT2. The presence of NAT2 (and NAT1) in the colons of fast acetylators probably explains why this phenotype is a risk modifier for the development of colon cancer.

Whether fast acetylators are protected from or predisposed to the cancer-causing effects of aromatic amines depends on the nature of the aromatic amine (bicyclic vs. heterocyclic) and on other important risk modifiers. Both the activation of aromatic amines by *N*-glucuronidation and the activation of *N*-hydroxy aromatic amines (hydroxylamines) by sulfonation are suspected of playing an important role in the incidence of bladder and colon cancer. These and other risk modifiers may explain why some epidemiological studies,

contrary to expectation, have shown that slow NAT2 acetylators are at increased risk for aromatic amine–induced bladder cancer, as was demonstrated for benzidine manufacturers in China (Hayes et al., 1993).

The *N*-acetylation of aromatic amines (a detoxication reaction) and the *O*-acetylation of *N*-hydroxy aromatic amines (an activation reaction) can be reversed by a microsomal enzyme called arylacetamide deacetylase (gene symbol AADAC) (Probst et al., 1994). This enzyme is similar to but distinct from the microsomal carboxylesterases that hydrolyze esters and amides, as described in the section "Carboxylesterases." AADAC can potentially alter the overall balance between detoxication and activation of aromatic amines.

Overall, it would appear that low NAT2 activity increases the risk of bladder, breast, liver, and lung cancers, and decreases the risk of colon cancer, whereas low NAT1 activity increases the risk of bladder and colon cancers and decreases the risk of lung cancer (Hirvonen, 1999). The individual risks associated with particular NAT1 and/or NAT2 acetylator genotypes are small, but they increase when considered in conjunction with other susceptibility genes and/or exposure to carcinogenic aromatic and heterocyclic amines. Because of the relatively high frequency of allelic variants of NAT1 and NAT2, the attributable risk of cancer in the population may be high (Hein et al., 2000).

Amino Acid Conjugation

There are two principal pathways by which xenobiotics are conjugated with amino acids, as illustrated in Fig. 6-68. The first involves conjugation of xenobiotics containing a carboxylic acid group with the *amino group* of amino acids such as glycine, glutamine, and taurine (see Fig. 6-57). This pathway involves activation of the xenobiotic by conjugation with coenzyme A (A), which produces a xenobiotic-CoA thioester that reacts with the *amino group* of an amino acid to form an amide linkage. The second pathway involves conjugation of xenobiotics containing an aromatic hydroxylamine (*N*-hydroxy aromatic amine) with the *carboxylic acid group* of such amino acids as serine and proline. This pathway involves activation of an amino acid by aminoacyl-tRNA synthetase, which reacts with an aromatic hydroxylamine to form a reactive *N*-ester (Kato and Yamazoe, 1994).

The conjugation of benzoic acid with glycine to form hippuric acid (see Fig. 6-4) was discovered in 1842, making it the first biotransformation reaction discovered (Knights et al., 2007; Badenhorst et al., 2014). The first step in this conjugation reaction involves activation of benzoic acid to an acyl-CoA thioester. This reaction requires ATP and is catalyzed by acyl-CoA synthetase (ATP-dependent acid:CoA ligase [AMP forming]). The second step is catalyzed by acyl-CoA:amino acid *N*-acyltransferase, which transfers the acyl moiety of the xenobiotic to the amino group of the acceptor amino acid. The reaction proceeds by a *ping-pong Bi–Bi* mechanism, and involves transfer of the xenobiotic to a cysteine residue in the enzyme with release of CoA, followed by transfer of the xenobiotic to the acceptor amino acid with regeneration of the enzyme. The second step in amino acid conjugation is analogous to amide formation during the acetylation of aromatic amines by NAT. Substrates for amino acid conjugation are restricted to certain aliphatic, aromatic, heteroaromatic, cinnamic, and arylacetic acids.

The ability of xenobiotics to undergo amino acid conjugation depends on steric hindrance around the carboxylic acid group, and by substituents on the aromatic ring or aliphatic side chain. In rats, ferrets, and monkeys, the major pathway of phenylacetic acid biotransformation is amino acid conjugation. However, due to steric hindrance, diphenylacetic acid cannot be conjugated with an amino acid, so the major pathway of diphenylacetic acid biotransformation in these three species is acyl glucuronidation. Bile acids are endogenous substrates for glycine and taurine conjugation. However, the activation of bile acids to an acyl-CoA thioester is catalyzed by a microsomal enzyme, cholyl-CoA synthetase, and conjugation with glycine or taurine is catalyzed by the cytosolic enzyme, bile acid-CoA:amino acid *N*-acyltransferase (BACAT; gene symbol BAAT) (Falany et al., 1994; Testa and Krämer, 2008, 2010). BACAT is expressed at high levels in the liver, kidney, gallbladder, and intestine, with lower levels in the adrenal gland, muscle, lung, and brain, which suggests that it may have substrates other than bile acids (O'Byrne et al., 2003). In vitro studies show that BACAT can form glycine conjugates of long-chain fatty acids, and also possesses thioesterase activity toward the same substrates (O'Byrne et al., 2003). In contrast to bile acids, the conjugation of xenobiotics with CoA occurs mainly in mitochondria, which appear to contain multiple acyl-CoA ligases. There are three acid-thiol ligases that are involved in the formation of a xenobiotic acyl-CoA intermediate, namely, the short-, medium-, and long-chain acyl-CoA ligase (Testa and Krämer, 2008, 2010). These enzymes are also involved in endogenous fatty acid activation. Of particular importance to amino acid conjugation is the medium-chain [butyrate]-CoA ligase present in the mitochondrial matrix, which converts medium-chain fatty acids (C4-C12) to CoA thioesters to initiate β-oxidation (Knights et al., 2007). In humans, two distinct forms of medium-chain fatty acid CoA ligases have been characterized, HXM-A (48 kDa) and HXM-B (49 kDa), each of which has overlapping substrate specificities. Common substrates of HXM-A and HXM-B include benzoate, propionate, hexanoate, octanoate, valproate, and salicylate (Knights et al., 2007). The formation of xenobiotic acyl-CoA conjugates is interesting because of their potential to cause mitochondrial toxicity by inhibiting fatty-acid β-oxidation due to a combination of CoA sequestration and direct inhibition of acyl-CoA ligases (Knights et al., 2007; Testa and Krämer, 2008, 2010). Some xenobiotic acyl-CoA conjugates can also act as reactive electrophiles and form protein adducts with immunogenic potential (see the section "Glucuronidation and Formation of Acyl-CoA Thioesters"). The second step in the conjugation of xenobiotics with amino acids is catalyzed by cytosolic and/or mitochondrial forms of *N*-acyltransferase, expressed primarily in the liver and kidney (Knights et al., 2007). Amino acid conjugation is apparently catalyzed by separate *N*-acyltransferases specific for each amino acid (Gopaul et al., 2003). Glycine-*N*-acyltransferase and glutamine-*N*-phenylacetyltransferase have been isolated from human hepatic mitochondria (Gopaul et al., 2003).

There are several examples of xenobiotics that undergo amino acid conjugation as a major metabolic pathway, such as the hypolipidemic drug nicotinic acid (niacin) that is conjugated with glycine to form nicotinuric acid (Iwaki et al., 1996; Testa and Krämer, 2008, 2010). In humans, over 90% of a dose of acetylsalicylic acid (aspirin) is hydrolyzed to salicylic acid, of which 75% is excreted in urine as the glycine conjugate, salicyluric acid (Knights et al., 2007; Testa and Krämer, 2008, 2010). While benzoic acids and small analogs generally are conjugated with glycine, larger substrates such as 4-phenylbutanoic acid are generally conjugated with glutamine. 4-Phenylbutanoic acid is a drug used in the treatment of hyperammonemia caused by genetic errors in urea synthesis. Conjugation of 4-phenylbutanoic acid with glutamine contributes to nitrogen elimination under conditions of impaired urea synthesis (Kasumov et al., 2004; Testa and Krämer, 2008, 2010). Taurine (along with glycine) plays an important role in the conjugation of bile acids. The herbicide 4-chloro-2-methylphenoxyacetic acid (MCPA) forms both taurine and glycine conjugates in dogs, but only trace glycine conjugates in rats (Lappin et al., 2002; Testa and Krämer, 2008,

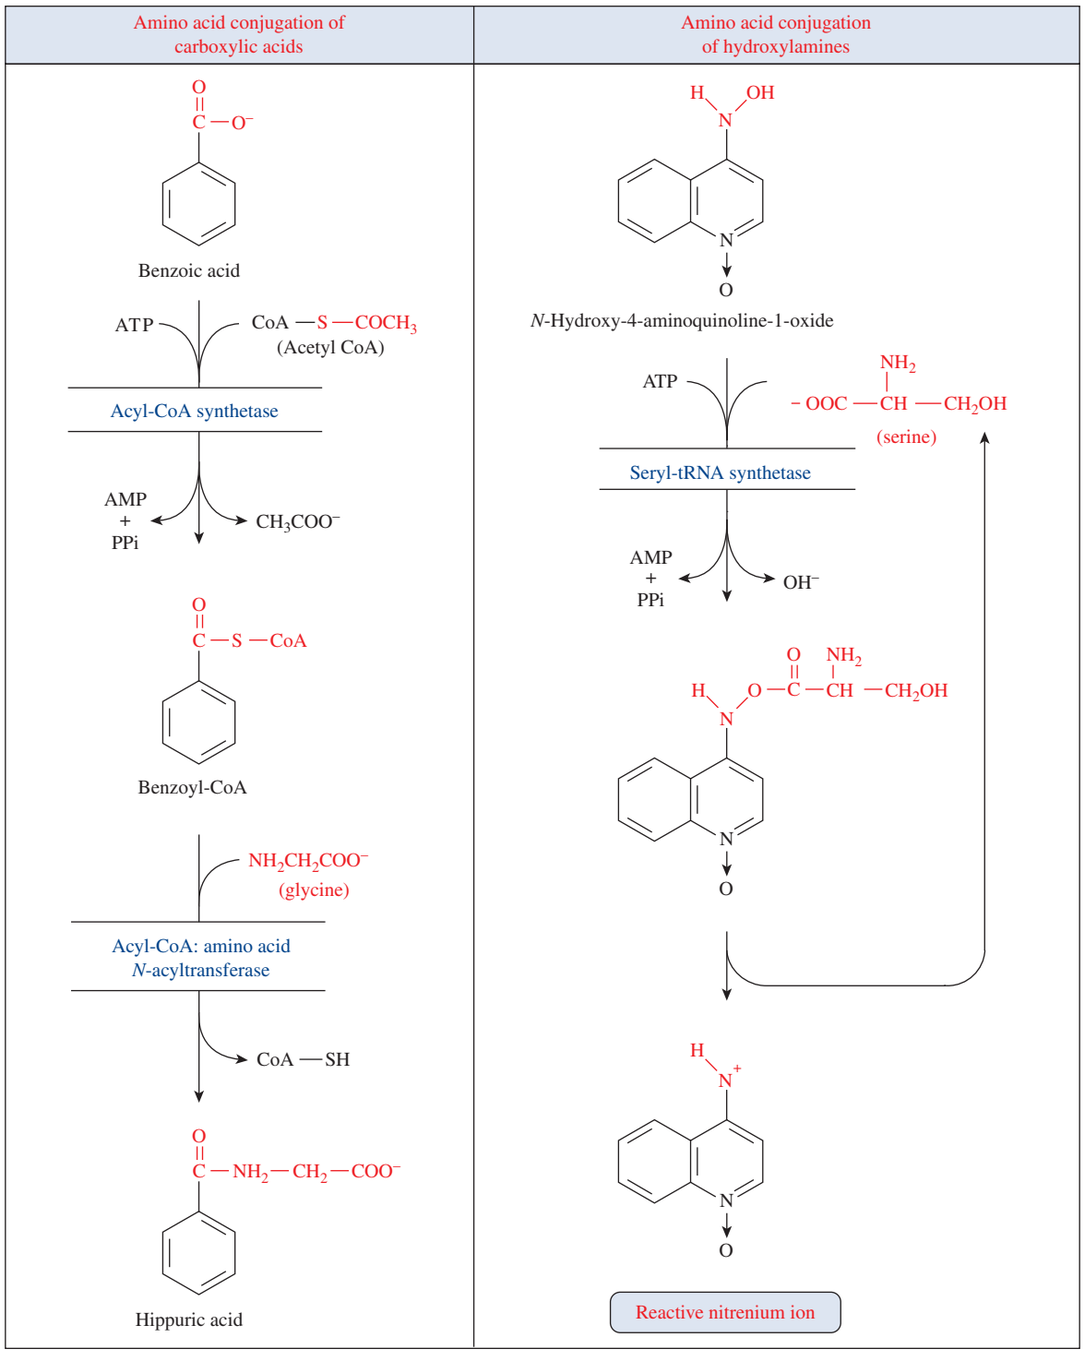

Figure 6-68. *Conjugation of xenobiotics with amino acids.*

2010). The PPARα agonist MRL-II exhibits dose-dependent formation of acyl glucuronides and taurine conjugates, major biliary metabolites in dogs, with lower doses favoring the formation of the taurine conjugate (Kim et al., 2004; Testa and Krämer, 2008, 2010). While few reports of xenobiotic taurine conjugates in humans exist, taurine conjugation of the NSAID ibuprofen is a minor metabolite eliminated in urine almost solely as the *S*-enantiomer (Shirley et al., 1994; Testa and Krämer, 2008, 2010).

An important difference between the amino acid conjugates of xenobiotics and bile acids is their route of elimination: bile acids are secreted into bile, whereas amino acid conjugates of xenobiotics are eliminated primarily in urine. The addition of an endogenous amino acid to xenobiotics may facilitate this elimination by increasing their ability to interact with the tubular organic anion transport system in the kidney. The precursor to amino acid conjugation, namely, the xenobiotic acyl-CoA thioester, is not transported out of the cell and is not detected in the bile, plasma, or urine, but it can be detected in tissue samples and in vitro test systems. The formation of xenobiotic acyl-CoA thioesters in adipose tissue (and their further metabolism to more complex lipid conjugates)

can be a relatively long-lived repository for certain acidic drugs. Consequently, in mass balance studies (i.e., in studies of the disposition of a radiolabeled drug) the formation of acyl-CoA thioesters and their lipid derivatives in adipose tissue can contribute to incomplete recovery of radioactivity in the case of acidic drugs and drugs that are extensively metabolized to one or more carboxylic acid–containing metabolites.

In addition to glycine, glutamine, and taurine, acceptor amino acids for xenobiotic conjugation include ornithine, arginine, histidine, serine, aspartic acid, and several dipeptides, such as glycylglycine, glycyltaurine, and glycylvaline. The acceptor amino acid used for conjugation is both species- and xenobiotic-dependent. For benzoic, heterocyclic, and cinnamic acids, the acceptor amino acid is glycine, except in birds and reptiles, which use ornithine. Arylacetic acids are also conjugated with glycine except in primates, which use glutamine. In mammals, taurine is generally an alternative acceptor to glycine. Taurine conjugation is well developed in nonmammalian species and carnivores. While most species conjugate bile acids with both glycine and taurine, cats and dogs conjugate bile acids only with taurine.

Amino acid conjugation of carboxylic acid–containing xenobiotics is an alternative to glucuronidation. Conjugation of carboxylic acid–containing xenobiotics with amino acids has long been considered a predominantly detoxication reaction. However, as outlined in the section "Glucuronidation and Formation of Acyl-CoA Thioesters," there is growing evidence that the toxicity of certain NSAIDs is due in part to the formation of reactive acyl-CoA thioesters (the precursors to amino acid conjugates), which represents an alternative activation pathway to the formation of reactive acyl glucuronides, as illustrated in Fig. 6-63. Amino acid conjugation of ibuprofen, ketoprofen, and related *profens* (2-substituted propionic acid NSAIDs) is significant for two reasons: it limits the formation of potentially toxic acyl glucuronides and it leads to chiral inversion (the interconversion of *R*- and *S*-enantiomers) (Shirley et al., 1994). The latter reaction requires conversion of the profen to its acyl-CoA thioester, which undergoes chiral inversion by 2-arylpropionyl-CoA epimerase (this involves the intermediacy of a symmetric, conjugated enolate anion). Chiral inversion may explain why the *R*- and *S*-enantiomers of several profen NSAIDs have comparable anti-inflammatory effects in vivo, even though the *S*-enantiomers are considerably more potent than their antipodes as in vitro inhibitors of cyclooxygenase (the target of NSAID therapy). There is also evidence that the acyl-CoA thioesters of the *R*-enantiomers are pharmacologically active and contribute to the therapeutic effect by inhibiting COX-2 (Neupert et al., 1997; Levoin et al., 2004; Testa and Krämer, 2008, 2010). In general, amino acid conjugation is a high-affinity–low-capacity reaction, whereas glucuronidation is a high-capacity–low-affinity reaction. At low substrate concentrations, amino acid conjugation can be the predominant reaction.

Amino acid conjugation of *N*-hydroxy aromatic amines (hydroxylamines) is an activation reaction because it produces *N*-esters that can degrade to form electrophilic nitrenium and carbonium ions (Anders, 1985; Kato and Yamazoe, 1994). Conjugation of hydroxylamines with amino acids is catalyzed by cytosolic aminoacyl-tRNA synthetases and requires ATP (Fig. 6-68). Hydroxylamines activated by aminoacyl-tRNA synthetases include *N*-hydroxy-4-aminoquinoline 1-oxide, which is conjugated with serine, and *N*-hydroxy-Trp-P-2, which is conjugated with proline. (*N*-Hydroxy-Trp-P-2 is the *N*-hydroxylated metabolite of Trp-P-2, a pyrolysis product of tryptophan [see Table 6-18].) It is now apparent that the hydroxylamines formed by the CYP-dependent *N*-hydroxylation of aromatic amines can potentially be activated by numerous reactions, including *N*-glucuronidation by UGTs (Fig. 6-62), *O*-acetylation by NAT (Fig. 6-16), *O*-sulfonation by SULT (Fig. 6-64), and conjugation with amino acids by seryl- or prolyl-tRNA synthetase (Fig. 6-68).

Various amino acid conjugates of valproic acid, including glutamine, glutamate, and glycine conjugates, have been detected in urine, plasma, and cerebrospinal fluid (CSF) of patients administered this antiepileptic drug (Gopaul et al., 2003). CSF concentrations of the glutamine and glutamate conjugates of valproic acid were five and nine times higher than in plasma, which suggests that these conjugation reactions in the brain decrease levels of the excitatory neurotransmitter glutamic acid and decrease the incidence of seizure (Gopaul et al., 2003). Taken together, these data suggest that amino acid conjugation in the brain may play a role in the mechanism of action of valproic acid.

Glutathione Conjugation

The preceding section described the conjugation of xenobiotics with certain amino acids, including some simple dipeptides, such as glycyltaurine. This section describes the conjugation of xenobiotics with the tripeptide glutathione (GSH) in a reaction also known as glutathionylation, which is fundamentally different from other conjugation reactions. While glucuronidation, sulfonation, and all of the other previously described conjugation reactions involve conjugation of nucleophilic xenobiotics or their nucleophilic metabolites, GSH conjugation occurs with electrophilic xenobiotics or their electrophilic metabolites. GSH is composed of glycine, cysteine, and glutamic acid; the latter being linked to cysteine via the γ-carboxyl group, not the usual α-carboxyl group, as shown in Fig. 6-57. Glutathione transferase (GST) activity was first discovered as the enzyme-catalyzed conjugation of GSH with halogenated compounds such as chloronitrobenzenes and bromosulfophthalein (Mannervik et al., 2005; Higgins and Hayes, 2011). The activity was initially designated GSH *S*-aryltransferase, and GST activities toward other substrates such as alkyl halides and epoxides were called *S*-alkyl and *S*-epoxide transferases. The original names were later replaced with letter designations once the overlapping substrate specificity was described, and it was recognized that GSTs do not simply conjugate xenobiotics with GSH but also catalyze reactions such as hydroperoxide reduction (an example of which is shown in Fig. 6-22 as part of the metabolism of carbon tetrachloride), dehydrohalogenation (as shown in Fig. 6-24 [general mechanisms] and Fig. 6-25 [dechlorination of DDT]), thiolysis (the general mechanism for disulfide cleavage is shown in Fig. 6-18), disulfide interchange, and isomerization (Mannervik et al., 2005; Higgins and Hayes, 2011). Although the abbreviation "GST" has survived to describe the enzyme family, the term "glutathione *S*-transferase" is technically incorrect because the glutathionyl group (GS-) is transferred rather than a single sulfur atom (Mannervik et al., 2005); hence, the correct term is glutathione transferase. GSTs function endogenously as part of a defense mechanism against reactive oxygen species; GSTs reduce the formation of hydroperoxides of fatty acids, phospholipids, and cholesterol and protect against the redox cycling of many quinone-containing compounds by conjugating them with GSH (Hayes et al., 2005; Testa and Krämer, 2010). GSTs also play a role in other endogenous functions such as the degradation of aromatic amino acids, steroid hormone synthesis, eicosanoid synthesis (leukotrienes are GSH conjugates), and modulation of signaling pathways (Hayes et al., 2005; Higgins and Hayes, 2011; Oakley, 2011)

Substrates for glutathionylation include an enormous array of electrophilic xenobiotics, or xenobiotics that can be biotransformed to electrophiles. GSH conjugates are thioethers that form

by nucleophilic attack of GSH thiolate anion (GS^-) with an electrophilic carbon or heteroatom (*O*, *N*, and *S*) in the xenobiotic or its metabolite. Michael acceptors are also conjugated with GSH (discussed later in this section). The sulfhydryl group in GSH has a pK_a(A) value of ~9.0; hence, at physiological pH, only about 1% of GSH is present in the thiolate anion (GS^-) form. A primary function of GSTs is to lower the pK_a(A) of GSH by more than two orders of magnitude (to pK_a(A) 6 to 7), such that most (more than 50%) of the GSH bound to GST is in the reactive anionic form, which is stabilized by hydrogen bonding with a tyrosine, serine, or cysteine residue in the active site (Testa and Krämer, 2008, 2010). GSH, cysteine, *N*-acetylcysteine (NAC), and various analogs (esters and amides) are used in vitro to trap electrophilic metabolites formed by CYP in liver microsomes. In this system, which lacks the cytosolic GSTs, only about 1% of GSH is present in the thiolate anion (GS^-), compared with 6% of cysteine and up to 16% for certain cysteine esters, which is why chemicals other than GSH are widely used to trap electrophilic metabolites formed by CYP in vitro (Reed, 1985). Cysteine has sixfold greater ionization than GSH at physiological pH; however, the concentration of GSH in liver is about 50 times greater than that of cysteine, and its ionization is greatly increased by binding to GSTs.

The synthesis of GSH involves formation of the peptide bond between cysteine and glutamic acid, followed by peptide bond formation with glycine. The first and overall rate-limiting reaction is catalyzed by γ-glutamylcysteine synthetase (γ-GCL), the second by GSH synthetase. At each step, ATP is hydrolyzed to ADP and inorganic phosphate (Testa and Krämer, 2008, 2010). Due to the sheer multiplicity of GSTs, they cannot be collectively inhibited or induced; therefore, the importance of glutathionylation in xenobiotic toxicity in vivo is often assessed by altering levels of GSH. This can be achieved by (1) inhibiting GSH synthesis, (2) depleting GSH, or (3) increasing GSH levels through Nrf2 activation. Inhibition of GSH synthesis can be achieved with buthionine-*S*-sulfoximine (BSO), which inhibits γ-GCL, the enzyme that catalyzes the first reaction in GSH synthesis (Ballatori et al., 2009a). Michael acceptors such as diethyl maleate (DEA) and phorone are commonly used in vivo to deplete GSH levels in experimental animals. Other chemicals, such as 2-cyclohexen-1-one and 2-cyclohepten-1-one, selectively decrease cerebral GSH levels in comparison with BSO treatment (Masukawa et al., 1989; Yoneyama et al., 2008). Lastly several chemicals can activate Nrf2, which induces γ-GCL, the rate-limiting step in GSH synthesis. Nrf2 activators include butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA), ethoxyquin, and low doses of acetaminophen (Higgins and Hayes, 2011).

The conjugation of xenobiotics with GSH is catalyzed by GSTs in cytosol, microsomes, and mitochondria (Hayes et al., 2005; Higgins and Hayes, 2011; Oakley, 2011). Most GSTs were originally found in the soluble cell fraction, and they are referred to as cytosolic or soluble GSTs, even though they may also be found in the nucleus or peroxisomes (Mannervik et al., 2005; Higgins and Hayes, 2011; Oakley, 2011). The only mitochondrial GST found to date has traditionally been referred to as Kappa GST (detailed later in this section), and although it dimerizes (as do the cytosolic GSTs), Kappa GST has a structure that is distinct from the cytosolic GSTs and is also present in peroxisomes, which suggests that it is involved in fatty acid β-oxidation (Hayes et al., 2005; Mannervik et al., 2005; Morel and Aninat, 2011). The microsomal GSTs or MAPEGs, which stands for membrane-associated proteins in eicosanoid and glutathione metabolism, are an independent group of GSTs expressed in microsomes and mitochondria. It should also be noted that some GSTs have nonenzymatic functions such as binding of zeaxanthin in the retina and c-Jun N-terminal kinase 1 by GST P1-1, and were initially designated by other names (Mannervik et al., 2005). There are also other proteins that are homologous to some GSTs but are not yet known to serve as detoxication enzymes, such as the chloride intracellular channels (CLIC) (Mannervik et al., 2005; Littler et al., 2010). Proteins that were characterized and named were subsequently identified as GSTs, as was the case with GSH-dependent hematopoietic prostaglandin D synthase (HPGDS), now determined to be GST S1-1 due to similarities with the Sigma class GSTs expressed in nonmammalian organisms. The GSTs are present in most tissues, with high concentrations in the liver, intestine, kidney, testis, adrenal, and lung.

Substrates for GST share three common features: they are hydrophobic, they contain an electrophilic atom, and they react nonenzymatically with GSH at some measurable rate. The mechanism by which GST increases the rate of GSH conjugation involves deprotonation of GSH to GS^- by an active-site tyrosine or serine, which functions as a general base catalyst (Atkins et al., 1993; Dirr et al., 1994). In the case of the Omega class GSTs, the active site contains a cysteine residue (Mukherjee et al., 2006; Board, 2011). The concentration of GSH in the liver is extremely high (5 to 10 mM) relative to plasma (0.5 to 10 μM); hence, the nonenzymatic conjugation of certain xenobiotics with GSH can be significant (Testa and Krämer, 2008, 2010). However, some xenobiotics are conjugated with GSH stereoselectively, indicating that the reaction is largely catalyzed by GST. Like GSH, the GSTs are themselves abundant cellular components, accounting for up to 10% of the total cellular protein. These enzymes bind, store, and/or transport a number of compounds that are not substrates for GSH conjugation. The cytoplasmic protein formerly known as ligandin, which binds heme, bilirubin, steroids, azo-dyes, polycyclic aromatic hydrocarbons (PAHs), and thyroid hormones, is an Alpha class GST (Oakley, 2011).

As shown in Fig. 6-69, substrates for GSH conjugation can be divided into two groups: those that are sufficiently electrophilic to be conjugated directly and those that must first be biotransformed to an electrophilic metabolite prior to conjugation. The second group of substrates for GSH conjugation includes reactive intermediates (often formed by CYP) such as oxiranes (arene oxides and alkene epoxides), nitrenium ions, carbonium ions, and free radicals. The conjugation reactions themselves can be divided into two types: *displacement reactions*, in which GSH displaces an electron-withdrawing group, and *addition reactions*, in which GSH is added to an activated double bond or strained ring system. Table 6-24 provides examples of typical substrates for each of the characterized GSTs.

The displacement of an electron-withdrawing group by GSH typically occurs when the substrate contains halide, sulfate, sulfonate, phosphate, or a nitro group (i.e., good *leaving groups*) attached to an allylic or benzylic carbon atom. Displacement of an electron-withdrawing group from aromatic xenobiotics is decreased by the presence of other substituents that donate electrons to the aromatic ring ($–NH_2$, –OH, –OR, and –R). Conversely, such displacement reactions are increased by the presence of other electron-withdrawing groups (–F, –Cl, –Br, –I, $–NO_2$, –CN, –CHO, and –COOR). This explains why 1,2-dichloro-4-nitrobenzene and 1-chloro-2,4-dinitrobenzene, each of which contains three electron-withdrawing groups, are commonly used as substrates for measuring GST activity in vitro, and one or more members of all three GST families can catalyze this conjugation reaction (Hayes et al., 2005; Higgins and Hayes, 2011). GST can catalyze the *O*-demethylation of dimethylvinphos and other methylated organophosphorus compounds. The reaction is analogous to the interaction between methyliodide and GSH, which produces methylglutathione and iodide ion ($GS^- + CH_3I \rightarrow GS–CH_3 + I^-$). In this case, iodide is the leaving group. In

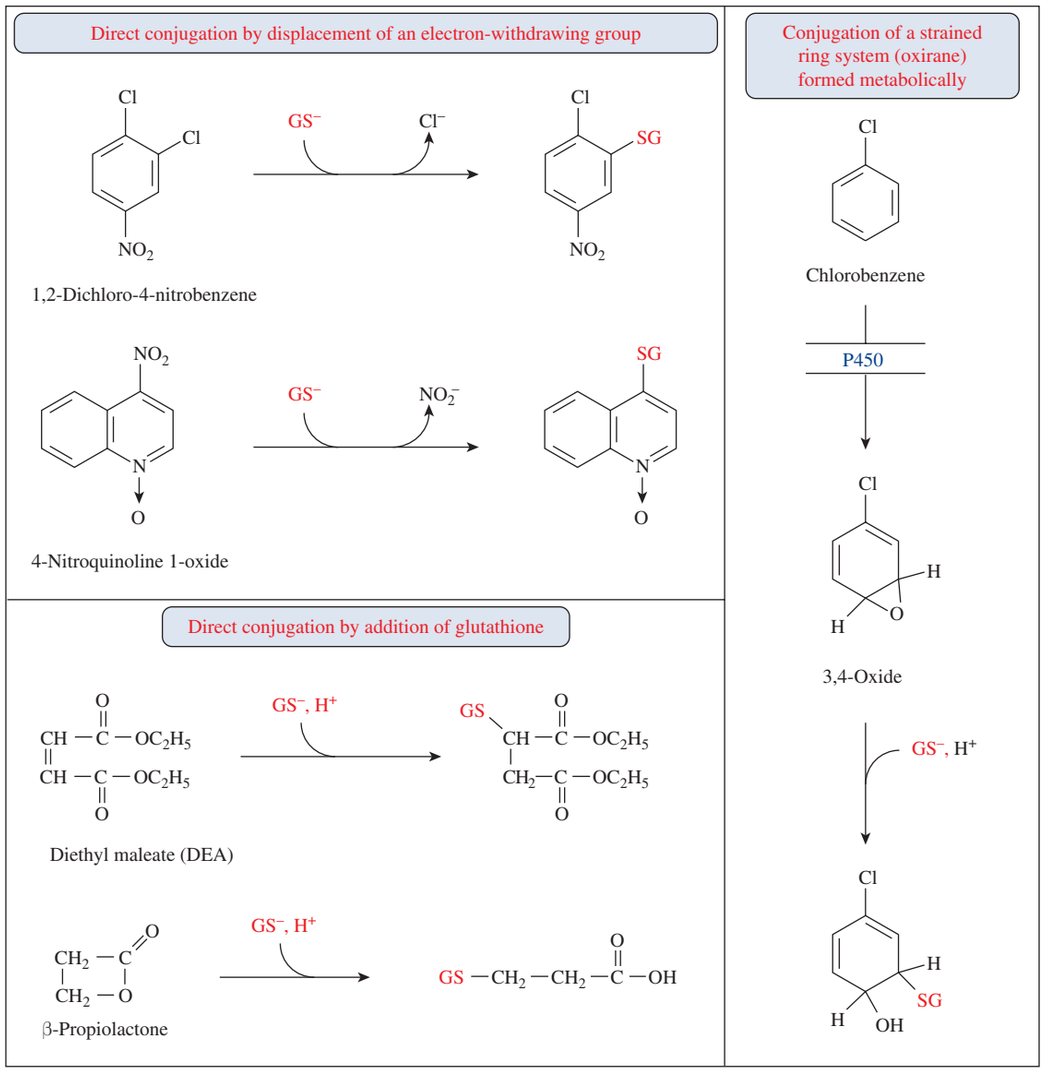

Figure 6-69. *Examples of glutathione conjugation of xenobiotics with an electrophilic carbon. GS− represents the anionic form of glutathione.*

the case of dimethylvinphos, the entire organophosphate molecule (minus the methyl group) functions as the leaving group.

The addition of GSH to a carbon–carbon double bond is also facilitated by the presence of a nearby electron-withdrawing group; hence, substrates for this reaction typically contain a double bond attached to –CN, –CHO, –COOR, or –COR (i.e., they are Michael acceptors). The double bond in diethyl maleate (DEA) is attached to two electron-withdrawing groups and readily undergoes a Michael addition reaction with GSH, as shown in Fig. 6-69. The loop diuretic, ethacrynic acid, contains an α/β-unsaturated ketone that readily reacts with GSH and other sulfhydryls by Michael addition. The conversion of acetaminophen to a GSH conjugate involves addition of GSH to an activated double bond, which is formed during the CYP-dependent dehydrogenation of acetaminophen to NAPQI, as shown in Fig. 6-39.

An interesting feature of GSH conjugation is the potential for nonenzymatic GSH conjugation in xenobiotic metabolism. The mechanism for this nonenzymatic activity is based on electrophilicity or nucleophilicity of potential reactants (Testa and Krämer, 2008, 2010). Electrophiles and nucleophiles are scaled according to their hardness or softness, and this determines whether a nonenzymatic or GST-catalyzed enzymatic reaction will be favored. Hard electrophilic sites are highly localized positive charges that maintain a high charge density during the approach of a nucleophilic reactant (i.e., they are not readily polarized). In contrast, soft electrophilic sites have a low charge density (i.e., a delocalized charge) and are easily polarized by an approaching nucleophilic reactant (Testa and Krämer, 2008, 2010). Because GSH acts as a soft nucleophile, it will react spontaneously with soft electrophiles, such as in the case of 1-4(nitrophenoxy)propane-2,3-oxide, which is a poor GST substrate, but reacts spontaneously with GSH (Testa and Krämer, 2008, 2010). Hard electrophiles are unlikely to react spontaneously with GSH and require the catalytic facilitation of GSTs (Testa and Krämer, 2008, 2010).

Arene oxides and alkene epoxides, which are often formed by CYP-dependent oxidation of aromatic hydrocarbons and alkenes, are examples of strained ring systems that open during the addition of GSH (Fig. 6-69). In many cases, conjugation of arene oxides with GSH proceeds stereoselectively, as shown in Fig. 6-70 for the 1,2-oxides of naphthalene. The GSH conjugates of arene oxides

Table 6-24

Human Glutathione Transferase Enzymes

GST FAMILY	CLASS	GENE	EXAMPLE ENZYMES	EXAMPLE SUBSTRATES
Cytosolic	Alpha	GSTA1	GST A1-1	Δ^5-ADD, BCDE, BPDE, busulfan, chlorambucil, DBADE, DBPDE, BPhDE, *N*-acetoxy-PhIP
		GSTA2	GST A2-2	CuOOH, DBPDE, 7-chloro-4-nitrobenz-2-oxa-1,3-diazole
		GSTA3	GST A3-3	Δ^5-ADD, Δ^5-pregnene-3,20-dione, DBPDE
		GSTA4	GST A4-4	COMC-6, EA, 4-hydroxynonenal, 4-hydroxydecenal
		GSTA5	GST A5-5	Unknown
	Mu	GSTM1	GST M1-1	*trans*-4-Phenyl-3-buten-2-one, BPDE, CDE, DBADE, *trans*-stilbene oxide, styrene-7,8-oxide
		GSTM2	GST M2-2	COMC-6, 1,2-dichloro-4-nitrobenzene, aminochrome, dopa O-quinone, $PGH_2 \rightarrow PGE_2$
		GSTM3	GST M3-3	BCNU, $PGH_2 \rightarrow PGE_2$
		GSTM4	GST M4-4	CDNB
		GSTM5	GST M5-5	CDNB
	Pi	GSTP1	GST P1-1	Acrolein, base propenals, BPDE, CDE, chlorambucil, COMC-6, EA, thio-TEPA
	Sigma	HPGDS	GST S1-1*	$PGH_2 \rightarrow PGD_2$
	Theta	GSTT1	GST T1-1	BCNU, butadiene epoxide, CH_2Cl_2, EPNP, ethylene oxide
		GSTT2	GST T2-2	CuOOH, menaphthyl sulfonate
	Zeta	GSTZ1	GST Z1-1	Dichloroacetate, fluoroacetate, 2-chloropropionate, maleylacetoacetate
	Omega	GSTO1	GST O1-1	Monomethylarsonic acid, dehydroascorbic acid
		GSTO2	GST O2-2	Monomethylarsonic acid, dehydroascorbic acid
Mitochondrial	Kappa	GSTK1	GSTK1-1	CDNB, CuOOH, (S)-15-hydroperoxy-5,8,11,13-eicosatetraenoic acid
Microsomal (MAPEGs)	Clan 1	MGST2	MGST2	CDNB, $LTA_4 \rightarrow LTC_4$, (*S*)-5-hydroperoxy-8,11,14-*cis*-6-*trans*-eicosatetraenoic acid
		MGST3	MGST3	CDNB, $LTA_4 \rightarrow LTC_4$,(S)-5-hydroperoxy-8,11,14-*cis*-6-*trans*-eicosatetraenoic acid
		LTC4S	LTC_4S	$LTA_4 \rightarrow LTC_4$
	Clan 2	PTGEs	PGES1	$PGH_2 \rightarrow PGE_2$
		MGST1	MGST1	CDNB, CuOOH, hexachlorobuta-1,3-diene
	Clan 3	ALOX5AP	FLAP	Arachidonic acid binding (nonenzymatic)

Abbreviations: Δ^5-ADD, Δ^5-androstene-3,17-dione; BCDE, benzo[g]chrysene diol epoxide; BCNU, 1,3-bis(2-chloroethyl)-1-nitrosourea; BPDE, benzo[a]pyrene diol epoxide; BPhDE, benzo[c]phenanthrene diol epoxide; CDE, chrysene-1,2-diol 3,4-epoxide; CDNB, 1-chloro-2,4-dinitrobenzene; COMC-6, crotonyloxymethyl-2-cyclohexenone; CuOOH, cumene hydroperoxide; DBADE, dibenz[a,h]anthracene diol epoxide; DBPDE, dibenzo[a,l]pyrene diol epoxide; EA, ethacrynic acid; EPNP, 1,2-epoxy-3-(p-nitrophenoxy)propane; N-acetoxy-PhIP, N -acetoxy-2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine.

**GST S1-1 is also the glutathione-dependent prostaglandin D_2 synthase.*

SOURCES: Data from Hayes et al. (2005), Mannervik et al. (2005), and Higgins and Hayes (2011).

may undergo rearrangement reactions, which restore aromaticity and possibly lead to migration of the conjugate to the adjacent carbon atom (through formation of an episulfonium ion), as shown in Fig. 6-70. Conjugation of quinones and quinoneimines with GSH also restores aromaticity, as shown in Fig. 6-39 for NAPQI, the reactive metabolite of acetaminophen. Compared with glucuronidation and sulfonation, conjugation with GSH is a minor pathway of acetaminophen biotransformation, even though the liver contains high levels of both GSH and GSTs. The relatively low rate of GSH conjugation reflects the slow rate of formation of NAPQI, which is catalyzed by CYP enzymes (Fig. 6-39).

GSH can also conjugate xenobiotics with an electrophilic heteroatom (*O*, *N*, and *S*) as shown in Fig. 6-71. In each of the examples shown in Fig. 6-71, the initial conjugate formed between GSH and the heteroatom is cleaved by a second molecule of GSH to form oxidized GSH, which is also known as glutathione disulfide (GSSG). The initial reactions shown in Fig. 6-71 are catalyzed by GST, whereas the second reaction (which leads to GSSG formation) generally occurs nonenzymatically. Analogous reactions leading to the reduction and cleavage of disulfides have been described previously (see Fig. 6-18). Some of the reactions shown in Fig. 6-71, such as the reduction of hydroperoxides to alcohols, can also be catalyzed by glutathione peroxidase (GPX), which is a selenium-dependent enzyme. For their role in the reduction of hydroperoxides, the GSTs are sometimes called nonselenium-requiring GPXs. For instance, one or more members of the mammalian cytosolic, microsomal, and mitochondrial GSTs exhibit GPX activity toward cumene hydroperoxide (Hayes et al., 2005). Cleavage of the nitrate esters of nitroglycerin releases nitrite, which can be converted to the potent vasodilator, nitric oxide (NO). The ability of sulfhydryl-generating chemicals to partially prevent or reverse tolerance to nitroglycerin suggests that GSH-dependent denitration may play

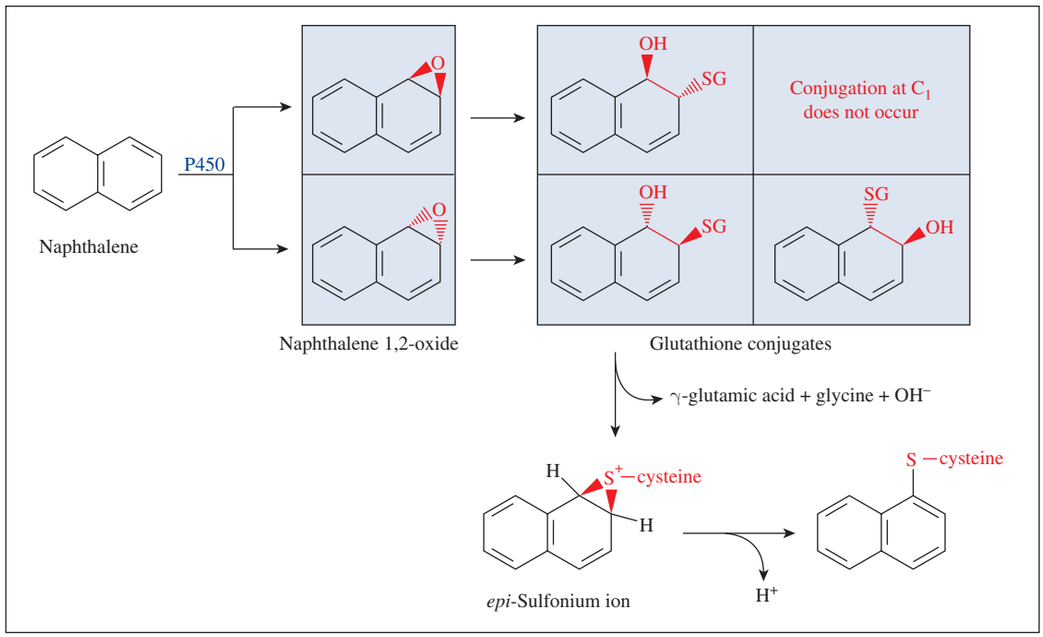

Figure 6-70. *Stereoselective conjugation of naphthalene 1,2-oxide and rearrangement of 2-naphthyl to 1-naphthyl conjugates.*

a role in nitroglycerin-induced vasodilation, although ALDH2 is recognized as the principal enzyme responsible for activating nitroglycerin as discussed in the section "Aldehyde Dehydrogenase" (Marchitti et al., 2008).

Cytosolic or mitochondrial GSTs catalyze two important isomerization reactions, namely, the conversion of the endoperoxide, PGH_2, to the prostaglandins PGD_2 and PGE_2 and the conversion of Δ^5 steroids to Δ^4 steroids, such as the formation of androstenedione from androst-5-ene-3,17-dione. Another physiological function of GST is the synthesis of leukotriene C_4, which is catalyzed by the microsomal GSTs, namely, MGST2, MGST3, and LTC_4S (see Table 6-24).

GSH conjugates formed in the liver can be effluxed into bile by MRP2 on the canalicular membrane, or they can be transported into blood by various transporters on the sinusoidal membrane such as MRP1, MRP3, MRP4, MRP5, and MRP6 (Giacomini and Sugiyama, 2006; Ballatori et al., 2009a; Klaassen and Aleksunes, 2010). MRP7 and MRP8 have also been implicated in the transport of GSH conjugates (Ballatori et al., 2009a). GSH itself is often cotransported with other xenobiotics or xenobiotic metabolites, namely, by MRP2 into bile, and by MRP1, MRP4, and MRP5 into blood (Ballatori et al., 2009a). This cotransport is exemplified by drugs such as vincristine, etoposide, and vinblastine, each of which stimulates MRP-mediated GSH transport (Ballatori et al., 2009a). BCRP is also involved in GSH transport (Brechbuhl et al., 2010). Furthermore, GST and MRP overexpression can act synergistically to confer multiple-drug resistance in many cancers, and can affect the efficacy of chemotherapeutic drugs such as chlorambucil, etoposide, ethacrynic acid, vincristine, and doxorubicin (Sau et al., 2010).

GSH conjugates can be converted to mercapturic acids (*N*-acetylcysteine conjugates) in the kidney and excreted in urine. As shown in Fig. 6-72, the conversion of GSH conjugates to mercapturic acids involves the sequential cleavage of glutamic acid and glycine from the GSH moiety, followed by *N*-acetylation of the resulting cysteine conjugate. The first two steps in mercapturic acid synthesis are catalyzed outside the cell by two membrane-bound enzymes on the luminal surface of the proximal tubule of the kidney (and the bile ducts of the liver), namely γ-glutamyltransferase (GGT; aka γ-glutamyltranspeptidase), which cleaves the glutamic acid residue, and alanyl aminopeptidase (ANPEP), which cleaves the glycine residue. After hydrolysis, the xenobiotic, now conjugated only to cysteine, is transported into the proximal tubule, where it is *N*-acetylated to a mercapturic acid by cytosolic NAT or deconjugated by mitochondrial β-lyase, as shown in Fig. 6-72. Mercapturic acids are transported back across the luminal surface of the proximal tubules for elimination in urine. Unconjugated GSH is also hydrolyzed by GGT and ANPEP to prevent loss of circulating GSH in urine. The process is remarkably efficient, as evidenced by the observation that treatment of rats with L-γ-glutamyl-(*O*-carboxy)-phenyl-hydrazine, an irreversible inhibitor of GGT, resulted in a 3000-fold increase in the urinary excretion of GSH (Griffith and Meister, 1979). Sequential hydrolysis by GGT and ANPEP is involved in leukotriene metabolism. Leukotriene C_4, a GSH conjugate, is hydrolyzed by GGT to leukotriene D_4, a cysteinylglycine conjugate, which in turn is hydrolyzed by ANPEP to leukotriene E_4, a cysteine conjugate.

Hydrolysis of GSH conjugates at the luminal membrane of proximal tubules followed by active uptake of the resulting cysteine conjugates into the proximal cells of the kidney plays a key role in the nephrotoxicity of certain xenobiotics. Nephrotoxicity is the dose-limiting toxicity of the anticancer drug cisplatin, which is conjugated with GSH. After hydrolysis by GGT and ANPEP in the lumen of the proximal tubule, the cysteine conjugate of cisplatin is actively transported into the proximal tubular cells, where it is converted by β-lyase to a highly reactive thiol that is toxic to kidney cells (Zhang and Hanigan, 2003). Cisplatin nephrotoxicity is not observed in GGT knockout mice or in mice treated with the GGT inhibitor acivicin (Hanigan et al., 1994, 2001). The antiretroviral drug efavirenz is nephrotoxic to rats and mice but not monkeys or humans. A sulfate conjugate of efavirenz is conjugated with GSH by a rodent-specific GST. Hydrolysis of the GSH conjugate by GGT and ANPEP followed by active transport of the cysteine

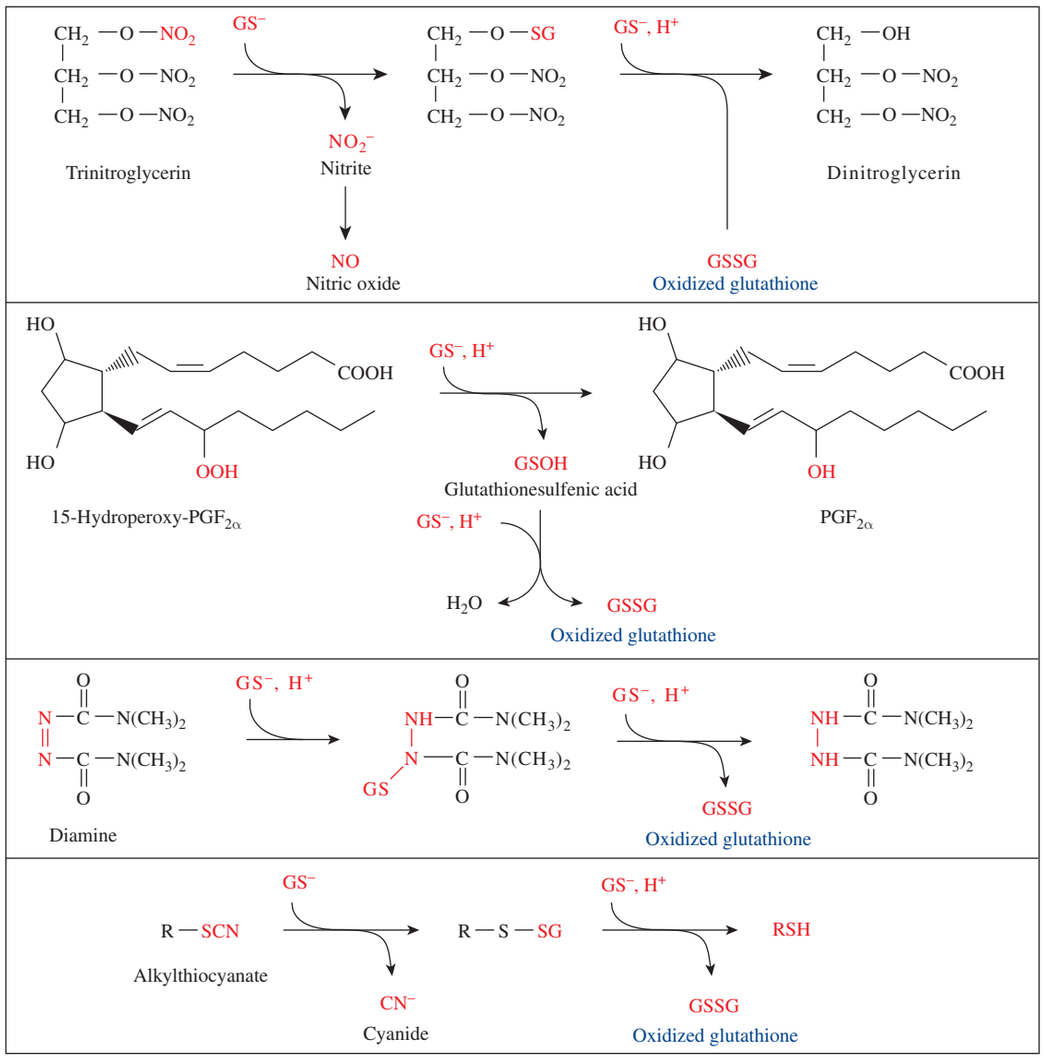

Figure 6-71. *Examples of glutathione conjugation of electrophilic heteroatoms.*

conjugate into the proximal cells of the kidney efficiently delivers high concentrations of efavirenz sulfate to the kidney, which results in nephrotoxicity in rodents but not primates (Mutlib et al., 1999, 2000). A similar mechanism (i.e., hydrolysis of GSH conjugates by membrane-bound GGT and ANPEP followed by active transport of the cysteine conjugate) accounts for the nephrotoxicity of a number of halogenated compounds, such as trichloroethene and hexachloro-1,3-butadiene, and other xenobiotics, as discussed later in this section (Dekant, 2001).

Cytosolic GSTs are dimers, typically composed of identical subunits (M_r 23–29 kDa), although some forms are heterodimers. Each subunit contains 199 to 244 amino acids and one catalytic site. The general structural features of cytosolic GSTs include an N-terminal thioredoxin-like domain (with βαβαβαβα topology) and a C-terminal domain consisting of α-helices (Oakley, 2011). Mitochondrial GSTs are also dimeric with 226 amino acids per subunit. The microsomal GSTs vary in their ability to form complex aggregates across the three groups of human MAPEGs. Numerous GST subunits have been cloned and sequenced, which forms the basis of a nomenclature system, as shown in Table 6-24 (Hayes et al., 2005; Mannervik et al., 1992; Hayes and Pulford, 1995; Whalen and Boyer, 1998; Higgins and Hayes, 2011). Each cytosolic and mitochondrial enzyme is assigned a two-digit number to designate its subunit composition. For example, the homodimers of subunits 1 and 2 are designated 1-1 and 2-2, respectively, whereas the heterodimer is designated 1-2. The soluble GSTs were initially arranged into four classes designated A, M, P, and T (which refer to Alpha, Mu, Pi, and Theta). Four additional classes were subsequently identified, namely, K (Kappa; the mitochondrial form), S (Sigma), Z (Zeta), and O (Omega) (Hayes and Pulford, 1995; Whalen and Boyer, 1998; Strange et al., 2000; Hayes et al., 2005; Higgins and Hayes, 2011; Oakley, 2011). None of these eight gene classes corresponds to the microsomal GSTs (MAPEGs), which appear to have evolved independently. By definition, the subunits in the different classes share less than 50% amino acid sequence identity. Generally, the subunits within a class are about 70% identical, but can share up to 90% sequence identity, and can form heterodimers, whereas the subunits in different classes are generally only about 30% identical. On the basis of structural similarity as well as the residues in the GSH-binding site that are involved in thiolate anion formation, the cytosolic GSTs can be divided into two groups: the more recently evolved Alpha, Mu, Pi, and Sigma classes that use

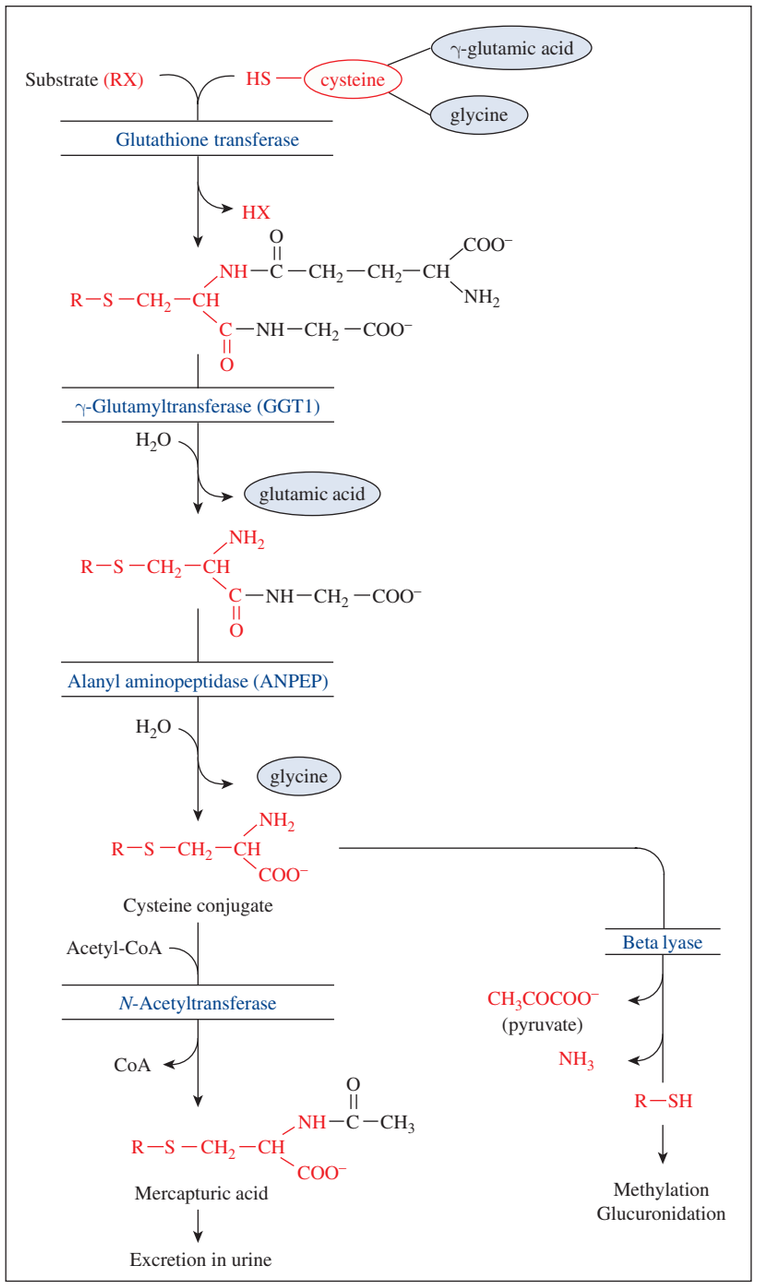

Figure 6-72. *Glutathione conjugation and mercapturic acid biosynthesis.*

a tyrosine residue near the N-terminus to activate GSH, and the older Theta, Omega, and Zeta classes that use either an N-terminal proximate serine or cysteine residue to activate GSH (Higgins and Hayes, 2011). Members of the Alpha and Mu classes can also form heterodimers with each other (Hayes et al., 2005). Affinity labeling studies with rat Alpha GSTs demonstrated the presence of a high-affinity, nonsubstrate binding site within the cleft between the two subunits of the dimer. Presumably, the cleft in heterodimers would be different from that in homodimers, which suggests the possibility that there is an evolutionary reason that the formation of heterodimers between Alpha and Mu subunits has been conserved (Hayes et al., 2005).

Several GSTs (as well as GGT) are overexpressed in various cancers, such as Alpha, Mu, Theta, Pi, and microsomal GSTs, which can confer resistance against many chemotherapeutic drugs (Hollman et al., 2016). For example, GST Alpha overexpression has been correlated with resistance to alkylating drugs (Sau et al., 2010). GST Mu overexpression is associated with chlorambucil resistance and a poor prognosis in childhood acute lymphoblastic leukemia (Sau et al., 2010). The microsomal GSTs have been shown to confer resistance to chlorambucil, melphalan, cisplatin, and doxorubicin treatment (Sau et al., 2010). GSTP1-1 overexpression, the most highly expressed GST in various cancers, is often associated with a poor prognosis and chemotherapeutic resistance

in ovarian, non-small-cell lung, breast, and colorectal cancers (Sau et al., 2010; Tew and Townsend, 2011). Two strategies have been adopted in the development of cancer therapies that specifically target cells that overexpress GSTs, namely (1) inhibition of GSTs and (2) activation of prodrugs by GSTs (or GGT) to form reactive metabolites (Ramsay and Dilda, 2014). Ezatiostat (Telintra or TLK199), which is currently in clinical trials for the treatment of myelodysplastic syndrome, is a GSH-peptidomimetic prodrug that is activated by cellular esterases to the selective GSTP1-1 inhibitor TLK117 (Sau et al., 2010; Tew and Townsend, 2011; Ramsay and Dilda, 2014). Although not commonly used due to its diuretic effects, ethacrynic acid inhibition of GSTs sensitizes cancer cells to chemotherapeutics (Sau et al., 2010). A synthetic GSH analog specifically inhibits GSTA1-1, whereas the 7-nitro-2,1,3-benzoxadiazole derivative NBDHEX is an inhibitor of GSTP1-1 that is not effluxed by transporters (Sau et al., 2010). Several other drugs have been shown to inhibit GSTs, such as drugs that act as NO donors (PABA/NO and oxathiazolylum-5-olate derivatives) and bombesin-sulfonamide derivatives (Sau et al., 2010). Canfosfamide (Telcyta or TLK286) is a GST-activated nitrogen mustard. This modified GSH analog is metabolized by GSTP1-1, which results in the release of two electrophilic fragments, GSH vinyl sulfone and tetrakis(chloroethyl)phosphorodiamidate, that induce apoptosis (Townsend and Tew, 2003; Rosen et al., 2004; Gonzalez and Tukey, 2006; Tew and Townsend, 2011). Clinical development of canfosfamide, for treatment of ovarian cancer, was halted by the FDA in 2007. Other drugs have also been developed to take advantage of activation by GSTs, such as brostallicin and ethacraplatin, which are derivatives of 2-crotonyloxymethyl-2-cycloalkenone (Sau et al., 2010). Like GST, GGT is also overexpressed in various cancer cells. Arsenic-based prodrugs (GSAO and darinaparsin) have been developed, which are activated by GGT (Ramsay and Dilda, 2014).

As is the case with many of the other xenobiotic-metabolizing enzymes, all of the GST enzymes are polymorphic and this likely contributes to interindividual differences in drug response or toxicity (Hollman et al., 2016). For example, the null phenotypes for GST Mu and GST Theta, GSTM1*0 and GSTT1*0, respectively, contribute to the drug-associated toxicities of several xenobiotics, such as carbamazepine, valproic acid, and troglitazone (Saruwatari et al., 2010; Ikeda, 2011). Therefore, individuals who are polymorphic for these enzymes (and also potentially for other GST allelic variants) are at an increased risk of toxicity by xenobiotics that are selectively biotransformed by specific GSTs. A large number of associations between genetic variants of GSTs (A1, M1, M3, M4, M5, O1, O2, P1, T1, and Z1) and multiple types of cancer, inflammatory diseases, immunological disorders, neurological disorders, age-related or metabolic disorders, and reproductive disorders have been described (Hollman et al., 2016).

The alpha GSTs are the major GSTs in the liver and kidney. They have basic isoelectric points. Rats express four GSTA genes, GSTA1–A4, whereas humans express five GSTA genes, GSTA1–A5. GST1*A and GST1*B are common variants of human GSTA1 (Hayes et al., 2005). GSTA1*A expression is higher than GSTA1*B, and individuals with the latter loss-of-function variant have improved rates of breast cancer survival, presumably due to increased efficacy of chemotherapeutic drugs (Ekhart et al., 2009). In contrast, GSTA2 variants *A to *D do not show much difference in enzymatic activity, whereas GSTA2*E is a loss-of-function variant (McIlwain et al., 2006). Rats express at least seven functional Mu subunits, designated GSTM1 through GSTM7. Humans express five subunits belonging to the Mu class of GSTs, designated GSTM1 through GSTM5. Human GSTM1, 3, and 4 are known to be polymorphic. In the case of GSTM1, the *A and *B allelic variants differ by a single amino acid; *A is a "basic variant" with lysine at residue 173, whereas *B is an "acidic variant" with asparagine at the corresponding site. There is also a GSTM1 deletion (*0) and a duplication (*1 × 2) (Hayes et al., 2005). The incidence of the GSTM1 deletion is high in Pacific Islander and Malaysian populations (i.e., 62% to 100%), intermediate in several other populations (i.e., 35% to 62% in those of European descent; 32% to 53% in those of Asian descent; 40% to 53% in those of Hispanic descent), and low in those of African descent (i.e., 23% to 41%) (Geisler and Olshan, 2001; Piacentini et al., 2011). GSTM1*0 has only a modest effect on the incidence of the lung, head, and neck cancers consistent with its high prevalence in various populations. The GSTM1*0 polymorphism has been linked to an increased susceptibility to certain inflammatory diseases (e.g., asthma) (Hayes et al., 2005). At least two allelic variants of GSTM3 and GSTM4 have also been identified. Members of the Mu class of GSTs have neutral isoelectric points. Human GSTM2 and GSTM3 are expressed in muscle and brain, respectively. The GSTM1*0 polymorphism is a risk factor for carbamazepine and valproic acid hepatotoxicity, whereas the double null phenotype of GSTM1*0 and GSTT1*0 is a risk factor for troglitazone hepatotoxicity (Ikeda, 2011; Saruwatari et al., 2010).

Humans and rats express one subunit belonging to the Pi class of GSTs, GSTP1, whereas mice have been found to express two Pi subunits, GSTP1 and GSTP2 (provisional). The human Pi enzyme is polymorphic, with at least four allelic variants reported (Hayes et al., 2005). The subunit encoded by GSTP1*B is seven times more active than that encoded by GSTP1*A in conjugating diol epoxides of polycyclic aromatic hydrocarbons (PAHs) (Strange et al., 2000). GSTP polymorphisms are known to influence susceptibility to carcinogens (including some pesticides), affect the response to chemotherapy used in the treatment of metastatic colon cancer and multiple myeloma, and modify the risk of acute myeloid leukemia which results from the successful treatment of Hodgkin disease, non-Hodgkin lymphoma, breast cancer, and ovarian cancer (Hayes et al., 2005; Liu et al., 2006b). GSTP polymorphisms that result in decreased activity have been implicated in an increased susceptibility to certain inflammatory diseases (e.g., asthma) (Hayes et al., 2005). In some cancers, such as prostate, breast, liver and blood cancers, GSTP1 is silenced by hypermethylation of a CpG-rich promoter region, which has been linked to the promotion of neoplastic transformation, such that low GSTP1 expression is a biomarker for multistep cancer development (Schnekenburger et al., 2014). Members of the Pi class of GSTs have acidic isoelectric points. They are expressed in the placenta, lung, gut, and other extrahepatic tissues. In rats, GSTP1 is one of several proteins (so-called preneoplastic antigens) that are overexpressed in chemical-induced tumors.

The Sigma class of GSTs is widely distributed in nature, and is present in many species including humans, mice, rats, chickens, insects, flatworms, and mollusks (Flanagan and Smythe, 2011). Sigma GSTs, also known as hematopoietic prostaglandin D synthases (HPGDS), are involved in the synthesis of prostaglandin in mammals, and catalyze the conversion of the cyclooxygenase product PGH_2 to PGD_2. Sigma subunits are also capable of conjugating GSH to a variety of aryl halide substrates and organic isothiocyanates and also have GPX activity toward cumene hydroperoxide (Flanagan and Smythe, 2011). The human Sigma class GST (HPGDS) is different from other cytosolic GSTs in that it is activated by divalent metal ions, such as Mg^{2+} and Ca^{2+}, binding at the center of the dimer interface formed by a group of six conserved Asp residues (Inoue et al., 2003; Flanagan and Smythe, 2011). Rats and humans appear to express a single Sigma GST (GSTS1, also

known as the GSH-dependent HPGDS). The tissue distribution of Sigma GST occurs in a species-specific manner. In mammals, high levels of Sigma GST are present in the spleen, bone marrow, placenta, lung, adipose, oviduct, and both dermal and epidermal layers of skin (Flanagan and Smythe, 2011). In rats, Sigma GST is highly expressed in bone marrow and spleen, whereas in humans it is highly expressed in the adipose tissue, placenta, lung, and fetal liver (Flanagan and Smythe, 2011). Immunohistochemical studies of Sigma GST (i.e., HPGDS) in rat, mouse, and human have shown that expression of the enzyme is limited to select cell types, namely, antigen-presenting cells, resident tissue and infiltrating mast cells, and T-helper (Th)-2 cells (Flanagan and Smythe, 2011). Sigma GST can play multiple roles in the immune response because the PGD_2 produced by Sigma GST (i.e., by HPGDS) can exert both proinflammatory and anti-inflammatory effects (Flanagan and Smythe, 2011). To block PGD_2 production associated with allergic inflammation, drugs have been or are currently being developed as Sigma GST (HPGDS) inhibitors, such as tranilast (*N*-(3,4-dimethoxycinnamoyl) anthranilic acid), which is an inhibitor of both HPGDS and LPGDS (lipocalin prostaglandin D synthase) (Flanagan and Smythe, 2011).

Humans express two subunits belonging to the Theta class of GSTs (GSTT1 and GSTT2), whereas rats and mice each express four subunits (GSTT1–4). GST Theta catalyzes the conjugation of mono and dihaloalkanes with GSH, in contrast to α-haloalkanoates and α, α-dihaloalkanoates which tend to be substrates of GST Zeta (Josephy, 2010). Due to the small active site of GST Theta, small xenobiotics are typical substrates of this enzyme, such as dichloromethane (Josephy, 2010). Additionally, analogous to the reaction shown in Fig. 6-24, GSTT1 is involved in the bioactivation of ethylene dibromide (an insecticide and gasoline additive) to an electrophilic sulfonium ion that can form adducts with macromolecules (Josephy, 2010). A GSTT1 deletion has been identified (GSTT1*0), which has a modest effect on the incidence of lung, head, and neck cancers, and has also been implicated in an increased susceptibility to certain inflammatory diseases (e.g., asthma) (Hayes et al., 2005) and coronary heart disease, especially in cigarette smokers (Song et al., 2017). The incidence of the GSTT1*0 is present in several populations, at a low to intermediate frequency (10% to 43%) in those of European and Mediterranean descent and a slightly higher frequency (20% to 45%) in those of African descent (Piacentini et al., 2011). The GSTT1 null allele, in conjunction with GST Mu deficiency, predisposes to troglitazone hepatotoxicity (Ikeda, 2011). Human GSTT2-2 conjugates ethacrynic acid with GSH and catalyzes the GSH-dependent reduction of cumene hydroperoxide, as well as the GSH-dependent sulfatase activity of 1-menaphthyl sulfate (Higgins and Hayes, 2011).

Zeta class GSTs are found in many species, such as plants, fungi, and mammals. Within mammals, there is also a wide tissue distribution of the protein with high levels predominantly in the liver and kidney (Board and Anders, 2011). A single Zeta subunit is expressed in rats, mice, and humans (GSTZ1), which dimerizes to form the functional enzyme GSTZ1-1. GSTZ1-1 is the same enzyme as maleylacetoacetate isomerase (MAAI), the enzyme that catalyzes the isomerization of maleylacetoacetate to fumarylacetoacetate, the penultimate step in tyrosine and phenylalanine catabolism (Board and Anders, 2011). GSTZ1-1 also catalyzes the GSH-dependent biotransformation of dichloroacetate (DCA) to glyoxylate ($CHCl_2$–COOH → CHO–COOH) (Board and Anders, 2011). Although GSH is required for the biotransformation of DCA to glyoxylate, it is not consumed as the GSTZ1-1-catalyzed nucleophilic attack of GSH on DCA yields *S*-(α-chlorocarboxymethyl) glutathione (GS–CHClCOOH), which in turn undergoes dehalogenation and facile hydrolysis to produce glyoxylate and GSH (Board and Anders, 2011). In all species examined, DCA inhibits its own metabolism by irreversibly inhibiting GSTZ1-1 through covalent modification of Cys_{16} by *S*-(α-chlorocarboxymethyl) glutathione (Board and Anders, 2011; James et al., 2017). DCA has several potential therapeutic applications (such as the treatment of inherited mitochondrial disorders that result in lactic acidosis, pulmonary hypertension and, by restoring aerobic glycolysis, several solid tumors) based on its ability to inhibit pyruvate dehydrogenase kinase. However, treatment with DCA is complicated by its auto-inhibition, which results in increased exposure to DCA with repeat dosing. While monohaloalkanes and dihaloalkanes tend to be substrates for GST Theta, a number of α-haloalkanoates and α,α-dihaloalkanoates have been identified as substrates for GSTZ1-1 (Board and Anders, 2011). At least four polymorphic variants of GSTZ1-1 have been identified in humans, with the haplotypes designated as GSTZ1A (Lys_{32}, Arg_{42}, Thr_{82}), GSTZ1B (Lys_{32}, Gly_{42}, Thr_{82}), GSTZ1C (Glu_{32}, Gly_{42}, Thr_{82}), and GSTZ1D (Glu_{32}, Gly_{42}, Met_{82}) (Board and Anders, 2011). GSTZ1C shows the highest allele frequency and has been designated the wild-type enzyme. GSTZ1A shows the highest rate of conversion of DCA to glyoxylate and is resistant to inactivation by DCA (Board and Anders, 2011). Genetically determined differences in DCA turnover may be significant if DCA is utilized in cancer therapy (Michelakis et al., 2010; Board and Anders, 2011). GSTZ1 knockout mice have increased levels of GSTA1, A2, M1, M5, P1, P2, and NQO1 in the liver, and undergo rapid weight loss, leucopenia, and death when provided 2% phenylalanine in drinking water (recall that GSTZ1-1 is the same enzyme as MAAI, the enzyme that catalyzes the isomerization of maleylacetoacetate to fumarylacetoacetate, the penultimate step in tyrosine and phenylalanine catabolism) (Board and Anders, 2011).

The Omega class of GST was initially identified through bioinformatics analysis of the expressed sequence tag (EST) database. Omega GSTs are present in many species including plants, yeast, nematodes, insects, and mammals (Board, 2011). Two Omega subunits have been identified in mice, rats, and humans (GSTO1 and GSTO2). GSTO1 and GSTO2 are also highly expressed in the mouse liver, heart, and kidney with wide distribution in other tissues (Board, 2011). The GSTOs differ from the other cytosolic GSTs in that they do not display the typical activity toward substrates such as 1-chloro-2,4-dinitrobenzene, dichloromethane, cumene hydroperoxide, or ethacrynic acid, but have some characteristics of glutaredoxins (GLRXs) (Board, 2011; Mukherjee et al., 2006). Interestingly, a mutation in GSTO1 (Cys_{32}Ala) significantly improves its GSH-conjugating activity with 1-chloro-2,4-dinitrobenzene (Board, 2011). Human GSTO1 shows thioltransferase activity and can catalyze the reduction of *S*-phenacylglutathione (a metabolite of tear gas), dehydroascorbate, and methylated arsenic species (Board, 2011). In fact, GSTO2 was originally identified in rats as dehydroascorbate reductase. The major component in tear gas 2-chloroacetophenone is converted to a GSH conjugate (*phenyl*-CO–CH_2Cl + GSH → *phenyl*-CO–CH_2–SG + HCl) that is further metabolized by GSTO1 to acetophenone (*phenyl*-CO–CH_2–SG + GSH → *phenyl*-CO–CH_3 + GSSG) (Board, 2011). Inasmuch as the reaction with *S*-phenacylglutathione is highly specific to GSTO1, a novel substrate was developed, namely, *S*-(4-nitrophenacyl)glutathione, that can be used in spectrophotometric assays to determine GSTO1 activity (Board, 2011). GSTO2 also exhibits thioltransferase activity and can catalyze the reduction of monomethylarsenate and dehydroascorbate, but not *S*-phenacylglutathiones (Board, 2011). Sulfonylurea cytokine-release inhibitory drugs (CRIDs) can bind to GSTO1 and inhibit IL-1β activation, suggesting GSTO1 involvement in a proinflammatory response (Board, 2011). GSTO1 can catalyze the glutathionylation and deglutathionylation of proteins.

This reversible, posttranslational modification of proteins may explain the requirement for functional GSTO1 in LPS-stimulated inflammatory signaling through the TLR4 receptor. The observation that ML175, a selective GSTO1 inhibitor, can block LPS-stimulated inflammatory signaling suggests that GSTO1 inhibitors represent a potential new class of anti-inflammatory drugs for the treatment of toxic shock and other inflammatory disorders (Board and Menon, 2016). Other chemicals have been shown to inhibit GSTO1 activity, such as tocopherol succinate, phenylsulfonate, omeprazole, and rifampicin (Bachovchin et al., 2009; Board, 2011). As Omega GSTs can reduce monomethylarsenic acid, they have been suggested to play a key role in arsenic biotransformation through the arsenic methylation pathway (Board, 2011). However, several studies have not supported a major role for GSTOs in overall arsenic biotransformation (Board, 2011). While most GSTs have a tyrosine or serine at the active site, GSTOs have a cysteine and an additional 19 amino acids at the N-terminus (Mukherjee et al., 2006; Board, 2011). Many polymorphisms have been detected in both GSTO1 and GSTO2, with five and four polymorphisms that result in amino acid changes, respectively (Mukherjee et al., 2006; Board, 2011). GSTO genes have also been associated with several neurological diseases, suggesting that variation of these GSTs may modify disease susceptibility or age of onset through a common pathological mechanism (Board, 2011).

The Kappa class of GSTs is an ancient protein family and represents a separate evolutionary pathway that has significant differences in function, localization, and structure than other soluble GSTs (Morel and Aninat, 2011). Harris et al. (1991) initially discovered and isolated GST Kappa from rat liver mitochondrial matrix. The Kappa subunit is a soluble, dimeric protein with a 36% sequence identity to GST Theta, and localized to both the mitochondria and peroxisomes (Morel and Aninat, 2011). A single Kappa subunit is expressed in mouse, rat, and humans, with the gene designated as GSTK1 in each species. The three-dimensional structure of the Kappa subunit is more similar to bacterial GSH-dependent and disulfide-bond-forming oxidoreductase (DsbA) than to the cytosolic GSTs. The Kappa subunit contains a thioredoxin-like domain but with a DsbA-like α-helical domain inserted between the α2 helix and the β3 strand (Oakley, 2011). GSTK1 is ubiquitously expressed in humans with the kidney, liver, adrenal gland, and adipose tissue expressing the most abundant levels (Morel and Aninat, 2011). Differential expression of GSTK1 has been seen between fetal and adult liver and brain tissues, indicating possible ontogenic regulation of GST Kappa (Morel and Aninat, 2011). In rodents it is present at high levels in the liver and stomach; moderate levels in the kidney, heart, and lung; and subsequent decreasing levels in the duodenum, jejunum, and ileum (Thomson et al., 2004; Knight et al., 2007; Morel and Aninat, 2011). GSTK1 expression in the heart shows marked gender differences, with females expressing twice as much Kappa subunit than males (Knight et al., 2007; Morel and Aninat, 2011).

Two human single nucleotide polymorphisms (SNPs) of GSTK1 have been identified in the 5′-flanking region of the GSTK1 gene located −1308 and −1032 bp from the transcription start site (Shield et al., 2010; Morel and Aninat, 2011). The −1308 SNP corresponds to a G to T transition, whereas the −1032 SNP corresponds to an alteration in a CpG methylation site (Shield et al., 2010; Morel and Aninat, 2011). The T allele variant (−1308 SNP) occurs with a 20% frequency in Asian populations (Morel and Aninat, 2011). The −1032 SNP has been demonstrated to cause a 38% decrease in GSTK1 promoter activity in HEK293 and HepG2 cells (Shield et al., 2010; Morel and Aninat, 2011). GSTK1 expression has been correlated with obesity; hence, GST Kappa may represent a new target for xenobiotics in the treatment of insulin resistance and related metabolic disorders (Morel and Aninat, 2011).

The microsomal GSTs are distinct from the soluble enzymes and have been referred to as the membrane-associated proteins in eicosanoid and glutathione metabolism (MAPEG) (Higgins and Hayes, 2011). Six human microsomal GSTs divided into three clans have been identified (see Table 6-24), which differ in their ability to form aggregates. For instance, MGST1 exists as a trimer, as does the other clan 2 MAPEG, namely, PGES1, whereas the clan 1 MAPEGs, LTC_4S, and MGST2, as well as the clan 3 MAPEG 5-lipoxygenase-activating protein (FLAP), can function as monomers, dimers, trimers, or more complex aggregates (Hayes et al., 2005; Martinez Molina et al., 2008; Higgins and Hayes, 2011). MGST1 conjugates xenobiotics with GSH and probably functions solely as a detoxication enzyme. It is a highly abundant microsomal protein (1% of total ER protein) in the human liver and the outer mitochondrial membrane (5% of outer mitochondrial membrane protein) in the rat liver (Morgenstern et al., 2011). MGST1 plays a role in the biotransformation of certain lipophilic reactive electrophiles and the reduction of membrane-embedded hydroperoxides with substrates that include halogenated hydrocarbons and phospholipid hydroperoxides (Morgenstern et al., 2011). The denitration of glyceryl trinitrate is another role for MGST1 (Morgenstern et al., 2011). While no specific substrates for MGST1 have been found, this MAPEG can be selectively activated with *N*-ethylmaleimide to determine its contribution toward overall GST activity (Morgenstern et al., 2011). Furthermore, MGST1 is the only GST that can utilize *N*-acetyl-L-cysteine as a cofactor instead of GSH (Morgenstern et al., 2011). MGST1 is involved in the formation of the mitochondrial permeability transition (MPT), suggesting a role for MGST1 in mitochondria-mediated cell death (Aniya and Imaizumi, 2011). It is also upregulated in many tumor types, overexpressed in many stem cells and stem-cell-like tumor cells, where it may be playing a protective role for these cells (Morgenstern et al., 2011). Other MAPEGs, such as MGST2 and MGST3, contribute to detoxication and synthesis of leukotriene C_4 (Hayes et al., 2005). FLAP does not have catalytic activity, but binds arachidonic acid and is essential for leukotriene synthesis. LTC_4S and PGES1 do not appear to be involved in xenobiotic metabolism (Hayes et al., 2005). Many SNPs have been identified in MGST1 and FLAP as well as diallelic variants in MGST3 in certain populations, but the biological significance has not yet been determined (Hayes et al., 2005).

The conjugation of certain xenobiotics with GSH is catalyzed by most classes of GST. For example, members of the Alpha, Kappa, Mu, and Pi classes of human cytosolic GSTs, as well as several of the MAPEG GSTs, all catalyze the conjugation of 1-chloro-2,4-dinitrobenzene. Other reactions are fairly specific for one class of enzymes (Hayes and Pulford, 1995). For example, the Alpha GSTs preferentially isomerize Δ^5 steroids to Δ^4 steroids and reduce linoleate and cumene hydroperoxide to their corresponding alcohols. The Mu GSTs preferentially conjugate certain arene oxides and alkene epoxides, such as styrene-7,8-epoxide. The Pi GSTs preferentially conjugate ethacrynic acid. Additional examples are shown in Table 6-24. However, individual members within a class of GSTs can differ markedly in their substrate specificity. In mice, for example, the Alpha GSTs composed of GSTA3 subunits can rapidly conjugate aflatoxin B_1 8,9-epoxide, whereas those composed of GSTA1 subunits are virtually incapable of catalyzing this reaction (Eaton and Gallagher, 1994).

In rodents, individual members of the Alpha and Mu classes of GSTs are inducible (generally two- to threefold) by 3-methylcholanthrene, phenobarbital, corticosteroids, oltipraz, and

various antioxidants (such as ethoxyquin and BHA). Several GST substrates (i.e., Michael acceptors) are GST inducers, as are certain nonsubstrates, such as hydrogen peroxide and other reactive oxygen species, all of which activate Nrf2 (Rushmore et al., 1991; Daniel, 1993; Nguyen et al., 1994; Hayes and Pulford, 1995; Hayes et al., 2005; Higgins and Hayes, 2011). Induction is usually associated with increased levels of mRNA due to transcriptional activation of the gene encoding a subunit of GST. Not all subunits are induced to the same extent (Higgins and Hayes, 2011).

The enhancer regions of the genes encoding some of the rodent GSTs (such as rat GSTA2-2) have been shown to contain a xenobiotic-responsive element (XRE), a putative phenobarbital-responsive element, a glucocorticoid-responsive element (GRE), and an antioxidant-responsive element (ARE, which is also known as the electrophile-responsive element [see Point 9 in the section "Principles of Xenobiotic Biotransformation"]). Accordingly, in rodents, certain GST subunits are regulated by both AhR and Nrf2 activators (i.e., by both *monofunctional* and *bifunctional* agents), as described previously for DT-diaphorase (see the sections "Quinone Reduction: NQO1 and NQO2" and "Induction of Cytochrome P450: Xenosensors"). Induction of GSTs by the Nrf2 activator sulforaphane is thought to be responsible, at least in part, for the anticancer effects of broccoli (Zhang et al., 1992; Higgins and Hayes, 2011). GSTA4 is induced in mice administered α-angeliclactone, butylated hydroxyanisole (BHA), ethoxyquin, indole-3-carbinol, limettin, and oltipraz (Hayes et al., 2005; Higgins and Hayes, 2011). In addition to inducing one or more GSTs, activation of Nrf2 by oxidative stress or exposure to electrophiles induces γ-GCL, which increases GSH levels in response to an initial decrease in GSH levels (see Point 9 in the section "Principles of Xenobiotic Biotransformation").

Factors that regulate the expression of GSTs in rodents may have similar effects in humans, but some differences have been noted. For example, the 5′ promoter region of Alpha GST in humans (GSTA1) lacks the ARE and XRE consensus sequences through which the corresponding rat enzyme is induced. However, such sequences appear to be present in the promoter region of human GSTM4 and GSTP1 genes (Hayes and Pulford, 1995; Whalen and Boyer, 1998; Higgins and Hayes, 2011). (A functional ARE is also present in the promoter region of human DT-diaphorase [NQO1].) Therefore, certain subunits of GSTs are inducible by a variety of mechanisms in rats, and other subunits appear to be inducible by similar mechanisms in humans. Species differences in GST regulation may also stem from differences in xenobiotic biotransformation, especially differences in the formation of electrophiles, Michael acceptors, and/or the production of oxidative stress. For example, coumarin is thought be an inducer of GSTP1 in rats because it is converted in the rat liver to reactive metabolites, namely, coumarin 3,4-epoxide and *ortho*-hydroxyphenylacetaldehyde (see Fig. 6-48). In contrast, the major route of coumarin biotransformation in humans is by 7-hydroxylation, which would not be expected to be associated with GST induction.

Conjugation with GSH represents an important detoxication reaction because electrophiles are potentially toxic species that can bind to critical nucleophiles, such as proteins and nucleic acids, and cause cellular damage and genetic mutations. All the enzymes involved in xenobiotic biotransformation have the potential to generate reactive intermediates, most of which are detoxified to some extent by conjugation with GSH. GSH is also a cofactor for GPXs, which play an important role in protecting cells against lipid and hemoglobin peroxidation. Resistance to toxic compounds is often associated with an overexpression of GST. Examples include the resistance of insects to DDT (see Fig. 6-25), of corn to atrazine, and of cancer cells to chemotherapeutic drugs.

GST is the major determinant of certain species differences in chemical-induced toxicity. For example, low doses of aflatoxin B_1 cause liver toxicity and tumor formation in rats but not mice, even though rats and mice convert aflatoxin B_1 to the highly reactive 8,9-epoxide at similar rates (this reaction is shown in Fig. 6-38). This species difference arises because mice express high levels of an Alpha class GST (GSTA3) enabling them to conjugate aflatoxin B_1 8,9-epoxide with GSH up to 50 times faster than rats (or humans, which are also considered a susceptible species) (Eaton and Gallagher, 1994). Mice become sensitive to the adverse effects of aflatoxin B_1 following treatment with chemicals that decrease GSH levels, such as diethyl maleate (DEA) (which depletes GSH) or buthionine-*S*-sulfoximine (BSO) (which inhibits GSH synthesis). Conversely, treatment of rats with inducers of certain GSTs, such as ethoxyquin, BHA, oltipraz, and phenobarbital, protects them from the hepatotoxic/tumorigenic action of aflatoxin B_1 (Hayes et al., 1994)

The conjugation of aflatoxin B_1 8,9-epoxide with GSH provides an interesting example of the stereospecificity with which certain GSH conjugation reactions can occur. CYP converts aflatoxin B_1 to a mixture of *exo*- and *endo*-8,9-epoxides (only a generic 8,9-epoxide is shown in Fig. 6-38, meaning the figure does not indicate whether the oxygen atom is above or below the plane of the ring system). Both enantiomeric epoxides are formed by liver microsomes from mice, rats, and humans, but only the *exo*-epoxide binds extensively to DNA (where it binds to the N^7 position of guanine). One or more mouse Alpha GSTs rapidly conjugate the *exo*-epoxide, which accounts for the resistance of this species to aflatoxin-induced hepatotoxicity and tumorigenicity (as described above). Rat and human GSTAs do not rapidly conjugate either the *exo*- or the *endo*-epoxide (with the exception of the inducible rat GST, which is not constitutively expressed in rats to any great extent). However, human GSTM1-1 can conjugate aflatoxin B_1 8,9-epoxide, but it preferentially conjugates the relatively innocuous *endo*-isomer (Wang et al., 2000).

Species differences in the detoxication of aflatoxin B_1 8,9-epoxide suggest that individual differences in GST may determine susceptibility to the toxic effects of certain chemicals. In support of this interpretation, a genetic polymorphism for GSTM1 has been identified, and individuals who are homozygous for the null allele (i.e., those with low GST activity due to complete deletion of the GSTM1 gene) appear to be at a moderately increased risk for cigarette-smoking-induced lung cancer, head and neck cancer, and possibly bladder cancer (Hayes and Pulford, 1995; Whalen and Boyer, 1998; Strange et al., 2000; Hayes et al., 2005). Depending on the ethnic group, 22% to 100% of the population is homozygous for the GSTM1 null genotype, which results in a complete lack of GSTM1 activity in all tissues. However, there is evidence that GSTM1 confers significant protection from breast cancer in individuals homozygous for a functional GSTM1 allele (Hayes et al., 2005). GSTT1 activity is absent from 11% to 58% of the population (depending on ethnicity) due to deletion of the GSTT1 gene, which appears to increase susceptibility to development of astrocytoma, meningioma, and myelodysplasia. When examined for their individual effect, these null genotypes generally have a small effect on disease susceptibility, with an odds ratio of 2 or less. However, the odds ratio can increase dramatically when these null GST genotypes are examined in conjunction with other genotypes or with environmental factors (such as exposure to carcinogens). For example, when the GSTM1 null genotype is combined with cigarette smoking and a particular CYP1A1 allele, the odds ratio can increase to 8.9 (in one study) or 21.9 (in another study). Polymorphisms that result in amino acid substitutions have been reported for most

human GST genes, some of which alter GST function. Some of these polymorphisms may also be risk modifiers for certain diseases in an analogous manner to the GSTM1 and GSTT1 null genotypes.

In some cases, conjugation with GSH enhances the toxicity of a xenobiotic (Monks et al., 1990; Dekant and Vamvakas, 1993; Testa and Krämer, 2008, 2010). Five mechanisms of GSH-dependent activation of xenobiotics have been identified, with the first four shown in Fig. 6-73. These mechanisms are (1) formation of GSH conjugates of haloalkanes, organic thiocyanates, and nitrosoguanides that release a toxic metabolite; (2) formation of GSH conjugates of vicinal dihaloalkanes that are inherently toxic because they can form electrophilic sulfur mustards; (3) formation of GSH conjugates of halogenated alkenes that are degraded to toxic metabolites by β-lyase in the kidney; (4) formation of GSH conjugates of quinones, quinoneimines, and isothiocyanates that are degraded to toxic metabolites by GGT1 and ANPEP in the kidney; and (5) cyclic GSH conjugation that leads to GSH depletion.

The first mechanism is illustrated by dichloromethane, which is conjugated with GSH to form the highly unstable *S*-chloromethylglutathione, which then breaks down to formaldehyde. Both formaldehyde and the GSH conjugate are reactive metabolites, and either or both may be responsible for dichloromethane-induced tumorigenesis in sensitive species. The rate of conjugation of dichloromethane with GSH is considerably faster in mice, which are susceptible to dichloromethane-induced tumorigenesis, than in rats or hamsters, which are resistant species. Other examples include the 1,1,3,3,3-pentafluoro-2-(fluromethoxy)prop-1-ene breakdown product of the general anesthetic sevoflurane. This breakdown product and its derivatives are conjugated to GSH, biotransformed to cysteine conjugates and mercapturic acids, which are then converted through β-lyase cleavage and thiol rearrangement to the highly reactive thioacyl fluoride (Testa and Krämer, 2008, 2010). This highly reactive metabolite can form adducts with proteins and may explain its associated nephrotoxicity (Testa and Krämer, 2008, 2010).

The second mechanism accounts for the toxicity of dichloroethane and dibromoethane. These vicinal dihaloalkanes are converted to GSH conjugates that can rearrange to form mutagenic and nephrotoxic episulfonium ions (sulfur half-mustards) (Fig. 6-73). Dichloroethane and dibromoethane can also be oxidized by CYP

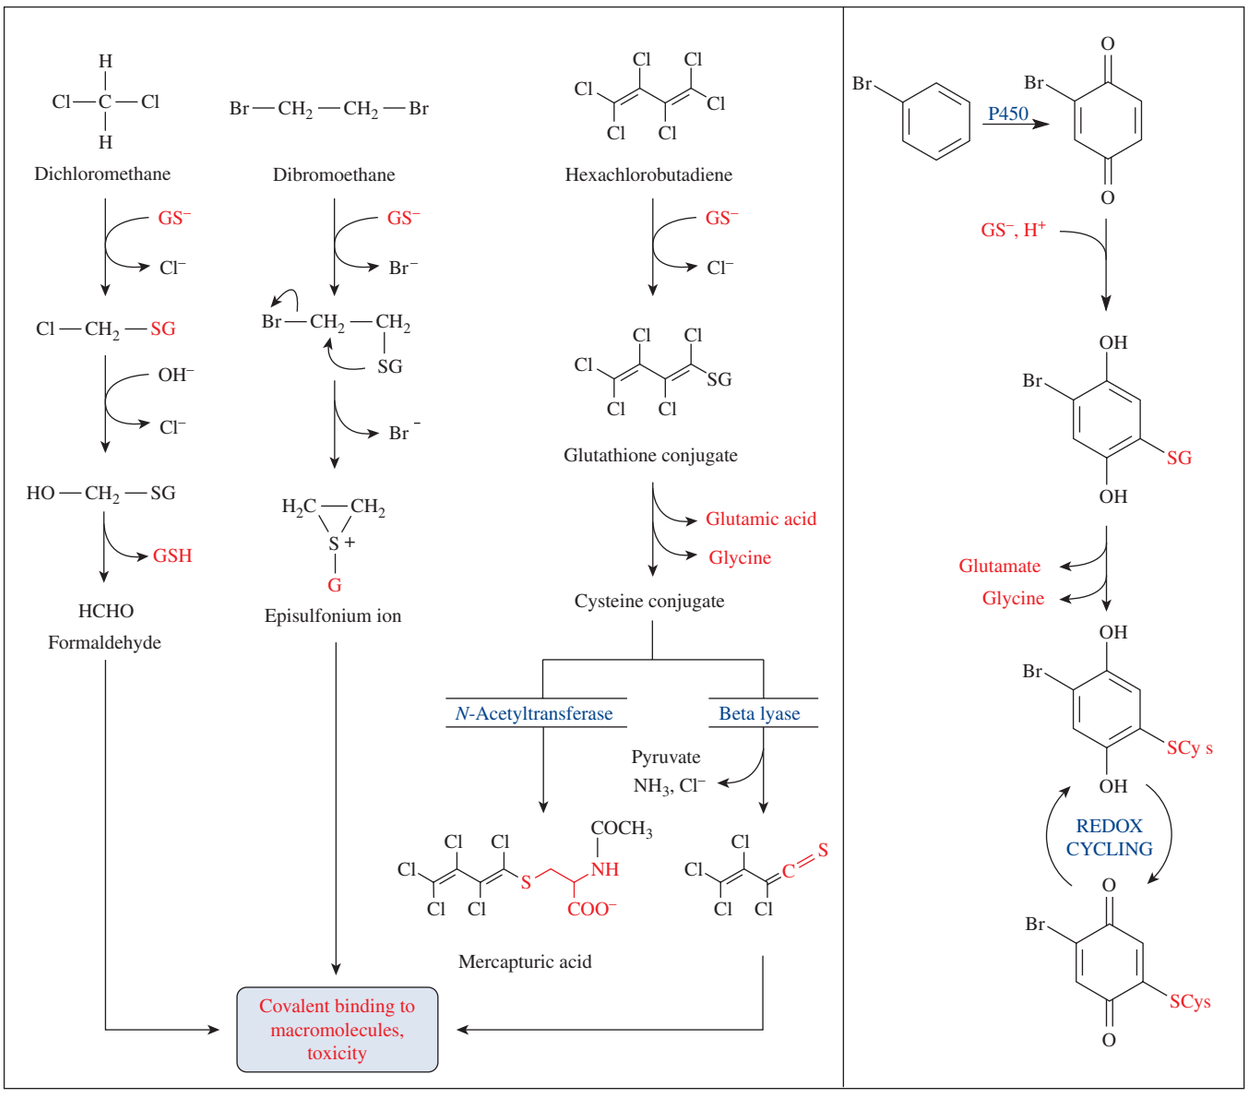

Figure 6-73. *Role of glutathione conjugation in the activation of xenobiotics to toxic metabolites.*

to chloroacetaldehyde and bromoacetaldehyde (by reactions analogous to those shown in Fig. 6-56). Either pathway can potentially account for the toxic and tumorigenic effects of these dihaloalkanes. However, the toxicity and DNA binding of dihaloalkanes are increased by factors that decrease their oxidation by CYP and increase their conjugation with GSH.

The third mechanism accounts for the nephrotoxicity of several halogenated alkenes. Several halogenated alkenes, such as hexachlorobutadiene, cause damage to the kidney tubules in rats, which leads to carcinoma of the proximal tubules. These nephrotoxic halogenated alkenes are conjugated with GSH and transported to the kidney for processing to mercapturic acids. The cysteine conjugates, which form by removal of glutamic acid and glycine, are substrates for *N*-acetyltransferase (NAT), which completes the synthesis of mercapturic acids, and cysteine-conjugate β-lyase (CCBL1), which removes pyruvate and ammonia from the cysteine conjugate to produce thionylacyl halides, thiiranes, thiolactones, and thioketenes. The early damage to renal mitochondria caused by halogenated alkenes is probably because CCBL1 is a mitochondrial enzyme.

The fourth mechanism accounts for the nephrotoxicity of bromobenzene, which causes damage to the proximal tubules in rats. Bromobenzene is oxidized by CYP in the liver to bromohydroquinone, which is conjugated with GSH and transported to the kidney (Fig. 6-73). The GSH conjugate is converted to the cysteine derivative by GGT1 and membrane ANPEP. Substitution of bromohydroquinones with cysteine lowers their redox potential and thereby facilitates their oxidation to toxic quinones. The cysteine conjugates of bromohydroquinone are thought to undergo redox cycling and cause kidney damage through the generation of reactive oxygen species. 4-Aminophenol is thought to cause kidney damage by a similar mechanism, except a benzoquinoneimine is involved in conjugation with GSH and subsequent damage to proximal tubules of the kidney. Treatment of rats with the GSH depletor, buthionine-*S*-sulfoximine (BSO), protects them against the nephrotoxic effects of 4-aminophenol, which implicates GSH conjugation in the activation of this compound.

The fifth mechanism occurs with moderately toxic allyl-, benzyl-, and phenethylisothiocyantes as well as sulforaphane formed from plant glucosinolates. These compounds are reversibly conjugated with GSH to form thiocarbamates which spontaneously degrade to their isothiocyanates upon export from the cell, which releases GSH. The isothiocyanate is then taken up by the cells again and the cycle can repeat until intracellular GSH is depleted. Once GSH levels are low, the compounds will tend to thiocarbamylate proteins, which can lead to cell death (Hayes et al., 2005).

Thiosulfate Sulfurtransferase (Rhodanese)

Cyanide forms naturally in leucocytes and neural cells, and also as a result of vitamin B_{12} metabolism, and is also encountered as a xenobiotic in plants containing cyanogenic glycosides, such as cassava, tobacco smoke, and pyrolysis of nitrile polymers or plastic (Billaut-Laden et al., 2006a; Libiad et al., 2015). Thiosulfate sulfurtransferase (TST) is a mitochondrial enzyme encoded by the TST gene that converts cyanide to the far less toxic metabolite, thiocyanate. The reaction involves transfer of sulfur from thiosulfate (or another sulfur donor) as follows:

$$\underset{\text{Cyanide}}{CN^-} + \underset{\text{Thiosulfate}}{S_2O_3^{2-}} \longrightarrow \underset{\text{Thiocyanate}}{SCN^-} + \underset{\text{Sulfite}}{SO_3^{2-}}$$

The sulfite produced by this reaction can be converted to sulfate by the molybdoenzyme, sulfite oxidase (see the section "Molybdenum Hydroxylases (Molybdoenzymes)"). Taking advantage of the TST reaction, thiosulfate has been used as an antidote against cyanide poisoning (Libiad et al., 2015). Cyanide can also be "detoxified" by binding to methemoglobin (the oxidized or ferric form of hemoglobin). 4-Dimethylaminophenol is used to induce methemoglobinemia as an antidote to cyanide poisoning because methemoglobin competes with cytochrome oxidase for the cyanide ion. However, 4-dimethylaminophenol is nephrotoxic to rats, presumably by a mechanism similar to that described above for the structural analog 4-aminophenol (see the preceding section and the section "Glutathione Conjugation"). TST also catalyzes the transfer of sulfane sulfur from glutathione persulfide (GSSH) to sulfite to form thiosulfate as part of the mitochondrial sulfide oxidation pathway (Libiad et al., 2015). The disulfide glutathione persulfide is formed by the transfer of sulfur from hydrogen sulfide to glutathione by sulfide quinone oxidoreductase (SQR).

In humans, TST is expressed at high levels in the liver, kidney, and particularly the colon where it plays a major role in the detoxication of hydrogen sulfide (which can reach concentrations of more than 3 mM) produced by anaerobic bacteria (Billaut-Laden et al., 2006a; Libiad et al., 2015). TST is also widely distributed in the central nervous system and may also play a role in the import of 5S rRNA into mitochondria (Smirnov et al., 2010). Several factors have been shown to induce TST, including resveratrol, α-lipoic acid, fungal (*Phellinus linteus*) polysaccharide extracts, and long-term low-dose irradiation, implicating TST in protection against persistent oxidative stress (Nakajima, 2015). Six allelic variants of TST have been identified, namely, TST*1B to TST*1F and TST*2, with the latter showing significantly reduced intrinsic metabolic clearance for thiocyanate formation (Billaut-Laden et al., 2006a). TST polymorphisms that decrease cyanide and hydrogen sulfide detoxication may ultimately become important in understanding certain diseases, such as ulcerative colitis and ALS. For instance, hydrogen sulfide release has been found to be three to four times higher in patients with ulcerative colitis when compared with healthy subjects, and is positively correlated with disease severity (Billaut-Laden et al., 2006a). Furthermore, it has been postulated that individuals with ALS display a disorder in cyanide metabolism because of the higher blood and urine levels of cyanide (Billaut-Laden et al., 2006a). Mimori et al. (1984) significantly decreased TST activity in cervical and thoracic spinal cords of patients with ALS compared with healthy subjects. Finally, TST has also been proposed as a target for the treatment of obesity and type 2 diabetes based on the observed inverse relationship between TST expression in adipose tissue and diabetes in rodents (Morton et al., 2016).

3-Mercaptopyruvate Sulfurtransferase

An additional pathway of cyanide detoxication involves the enzyme 3-mercaptopyruvate sulfurtransferase (encoded by the gene MPST) that converts cyanide to thiocyanate by the transfer of sulfur from 3-mercaptopyruvate as follows:

$$CN^- + \text{3-Mercaptopyruvate} \rightarrow \text{Thiocyanate} + \text{Pyruvate}.$$

The 3-mercaptopyruvate in this reaction is produced during cysteine metabolism by cysteine aminotransferase (Billaut-Laden et al., 2006b; Nagahara et al., 2015). MPST is both a cytosolic and mitochondrial enzyme and is expressed at high levels in the kidney, liver, heart, and erythrocytes (Billaut-Laden et al., 2006b).

Three allelic variants of MPST have been identified, namely, MPST*1B, MPST*1C, and MPST*2, with the latter showing little-to-no activity because it is a nonsense allele (Billaut-Laden et al., 2006b). While TST and MPST are related enzymes due to their

shared amino acid sequence identity and function in cyanide detoxification, MPST enzymatic activity has been shown to be induced specifically by diallyl disulfide, suggesting a separate mechanism of regulation for each enzyme (Nakajima, 2015).

Unusual Conjugation Reactions

In rare cases, xenobiotics can be biotransformed to unusual conjugates which can contribute to xenobiotic clearance. As shown in Fig. 6-74, the immunosuppressive drug 6-mercaptopurine (as well as its precursor azathioprine) is converted to 6-thioinosine monophosphate (TIMP) by hypoxanthine guanine phophoribosyltransferase (HGPRT) with phophoribosyl pyrophosphate (PRPP) as the phophoribosyl donor (Wielinga et al., 2002; Gearry et al., 2010; Hofmann et al., 2012). Similarly, to 6-mercaptopurine, 6-thiopurine can also be converted to a thionucleotide monophosphate (TNMP) (Wielinga et al., 2002). While the 6-thioguanine nucleotides are responsible for immunosuppressant activity, 6-methylmercaptopurine nucleotides have been associated with hepatotoxicity at high doses (Gearry et al., 2010).

Another example of an unusual conjugate is that of the immunosuppressant macrolide everolimus, which forms a phosphocholine conjugate as a major metabolite (ATG181) in both animals and humans (Zollinger et al., 2008). While phosphocholine esters of endogenous lipids, such as sphingomyelins or phosphatidylcholines, are common, phosphocholine conjugates of xenobiotics are rare. The addition of activated phosphocholine is catalyzed by the enzymes cholinephosphotransferase found in the Golgi apparatus as well as choline/ethanolaminephosphotransferase found in the endoplasmic reticulum and nuclear envelope; however, it is not known whether these enzymes also catalyze the phosphocholine conjugation of everolimus (Zollinger et al., 2008). Hepatitis C inhibitors containing a bicycle[1.1.1]pentane moiety are also conjugated with phosphocholine (Zhuo et al., 2016), whereas pimasertib, an inhibitor of MEK1/2 (the mitogen-activated protein kinase signaling pathway), is conjugated with phosphoethanolamine (Scheible et al., 2017).

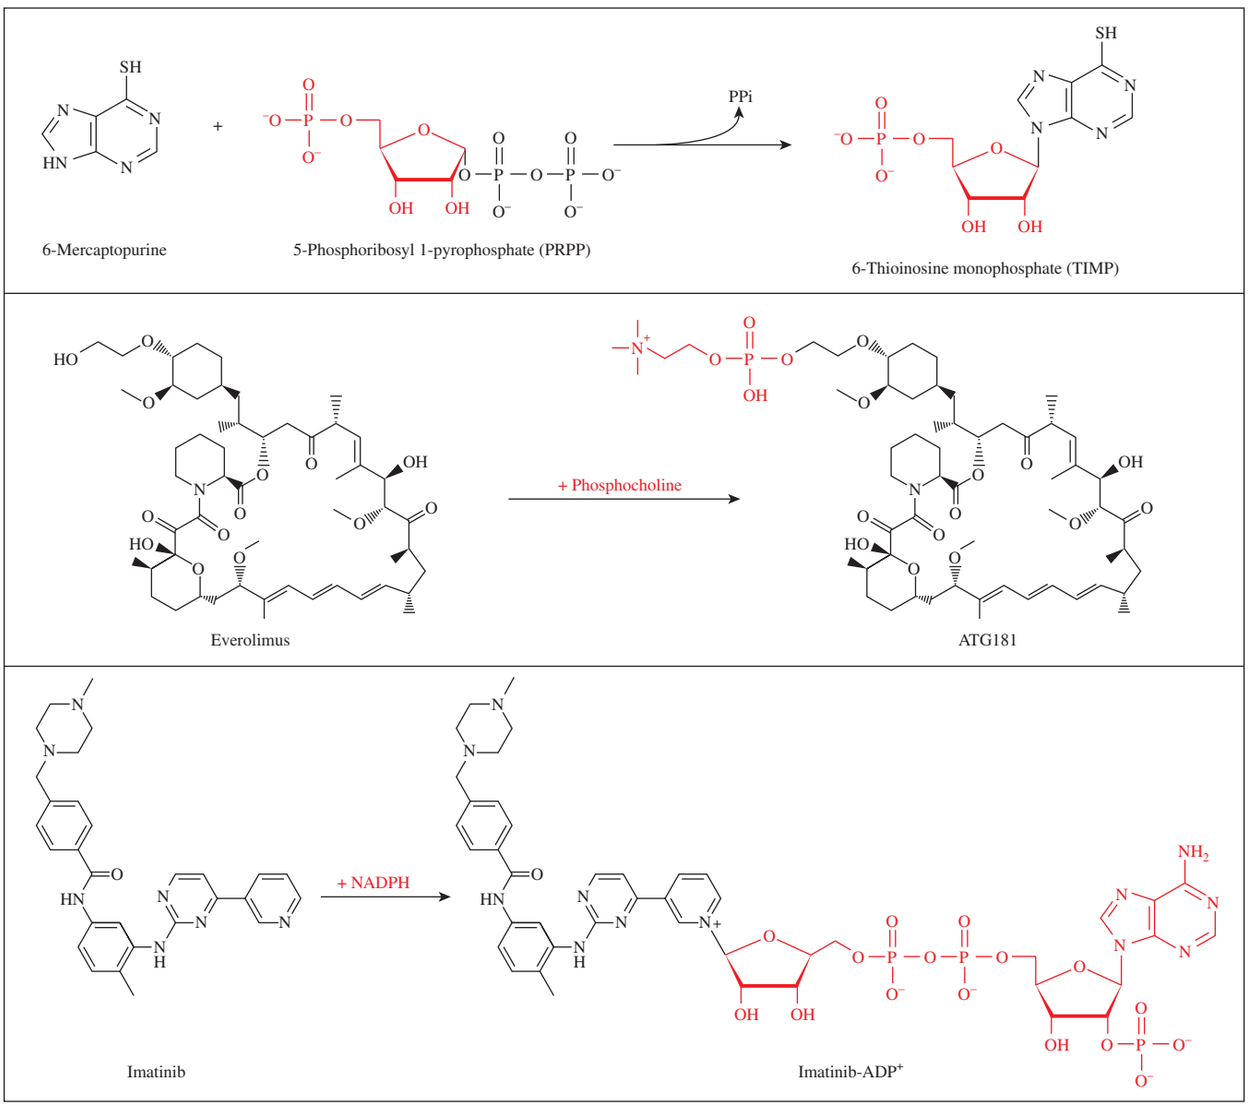

Figure 6-74. *Examples of unusual conjugation reactions.*

The hydroxyl group or a nitrogen atom in azoheterocyclic xenobiotics can be conjugated with ADP-ribose, the ADP moiety of which can be hydrolyzed by phosphatases to convert the ADP-ribose conjugate to a ribose conjugate (Fan et al., 2016). The ADP-ribosyltransferases (ART) responsible for the ADP-ribosylation of xenobiotics is known variously as NAD^+ hydrolase, NAD-glycohydrolase, nucleosidase, or NADase (EC 3.2.2.5), which use various nicotiminade cofactors including NAD, NADP, and/or NMN. Examples of substrates that undergo ADP-ribosylation are rifampin, imatinib, otenabant, continine, nicotinic acid, 4-ipomeanol, and nitrosamines such as 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) and 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL). Different forms of ART are thought to be responsible for ADP-ribosylation of xenobiotics in liver cytosol and endoplasmic reticulum (Fan et al., 2016). ADP-ribosylation is highly species specific and is mainly observed in rodents (i.e., imatinib, ipomeanol, and NNK/NNAL) but not in dogs, monkeys, or humans (Fan et al., 2016).

While single amino-acid conjugation is a well characterized metabolic pathway for xenobiotic metabolism (see the section "Amino Acid Conjugation"), xenobiotic conjugation to a peptide moiety other than glutathione is rare. The metabolism of lucanthone is an example of this unusual peptide conjugation. In human liver microsomes and in incubations with fungi, lucanthone undergoes desethylation or 4-methyl hydroxylation to yield desethyl lucanthone and hycanthone, respectively, and these products can be further metabolized (Mitchell et al., 2014). Lucanthone can also undergo sulfoxidation to yield lucanthone sulfoxide, the major urinary metabolite excreted by monkey. Lucanthone sulfoxide is conjugated with a peptide moiety, named miracil X, which was shown to be a unique human urinary metabolite (Mitchell et al., 2014). There are several other examples of peptide conjugation to xenobiotics, namely 3-phenoxybenzoic acid conjugation to dipeptide glycylvaline, quinaldic acid conjugates with glycylglycine and glycyltaurine, polyglutamyl conjugates of methotrexate and aminopterin, CCNU ((2-chloroethyl)-3-cyclohexyl-1-nitrosourea) peptide conjugate, DDA (4,4′-dichlorodiphenylacetic acid) peptide conjugate, and polypeptide conjugates of phenothiazine (Mitchell et al., 2014). However, the enzymatic pathways involved and the significance of these conjugates are not well established.

Succinylation has been shown to be a posttranslational modification of proteins (typically at lysine residues); however, succinylation of xenobiotics is rare (Zhang et al., 2011b). The only reported case of this conjugation reaction is that of mephedrone, which is succinylated in humans. In studies with human volunteers dosed with mephedrone, a novel mephedrone succinate conjugate was detected in urine, and proposed to form from the conjugation of succinic acid to nor-mephedrone (Pozo et al., 2015). Succinylation of xenobiotics is typically used as a prodrug strategy to produce drugs with favorable properties; however, succinylation as a mechanism of xenobiotic clearance is highly unusual (Pozo et al., 2015).

Another unusual conjugate is that of investigational anticancer agent β-lapachone, which forms a glucosylsulfate conjugate in mammals (Savage et al., 2008). Glucosidation and sulfonation of xenobiotics can readily occur (see the sections "Glucuronidation and Formation of Acyl-CoA Thioesters" and "Sulfonation") by UGT and SULT enzymes. However, typically these Phase 2 reactions are independent of each other and are not sequential to each other at the same metabolic site. In the case of β-lapachone, reduction by NOQ to a hydroquinone is followed by glucosidation, which in turn is followed by sulfonation of the glucose moiety (suspected to occur at glucose C6) forming the unusual glucosylsulfate conjugate (Savage et al., 2008). Glucosylsulfate conjugates have previously been observed in cotton plants treated with the insecticide profenofos and 2,4-dicholorphenoxyacetic acid; in sugar beets treated with phenmedipham, and in crustaceans exposed to 1-hydroxypyrene (Savage et al., 2008).

Lastly, the mechanism of xenobiotic conjugation to urea has been an area of some debate in the literature. These unusual conjugates have largely been considered as artifacts formed in urine through a nonenzymatic chemical reaction; however, there are reports of xenobiotic-urea metabolites found in bile and feces. An example of this is that of rosaramicin, where its urea metabolite 20-bisureidorosaramicin was found in dog bile and feces, as well as human feces, suggesting an enzymatic process in the formation of this metabolite (Mitchell, 2014). Xenobiotics that form urea conjugates include aminopyrine, formaldehyde, oxazepam, caroxazone, laropiprant, torcetrapib, isoproturon, and andrographolide (Mitchell, 2014). The significance of these conjugates and their mechanism of formation (chemical vs. metabolic) remain unclear.

Phosphorylation

Some drugs are intentionally designed to be phosphorylated by intracellular enzymes. For example, the anti-HIV drug zidovudine (AZT) is converted to a triphosphate nucleoside by enzymes in the salvage pathway (nucleoside kinase, nucleoside monophosphate kinase [NMK], and nucleoside diphosphate kinase [NDK]). A rare example of a non-nucleoside mimetic that undergoes phosphorylation is AZ2381, a tankyrase inhibitor, which is phosphorylated at its primary alcohol moiety by red blood cells from mice and, to a lesser extent, rat, dog, and human (Gu et al., 2017). However, phosphorylation of xenobiotics is the exception rather than the rule. All conjugation reactions ultimately require ATP, either to activate the xenobiotic for conjugation with GSH or amino acids or to synthesize high-energy cofactors such as UDPGA and PAPS. The process is inefficient in that several ATP molecules (or their equivalent) are used to synthesize each cofactor molecule. The question arises: why is ATP not used directly by conjugating enzymes? In other words, why are xenobiotics rarely phosphorylated directly (with the exception of nucleoside mimetics like zidovudine and the tankyrase inhinitor AZ2381), which would require less ATP and would achieve the goal of converting xenobiotics to water-soluble conjugates? It is difficult to be certain why this does not occur, but four reasons suggest themselves. First, if xenobiotics could be phosphorylated, high intracellular levels of a xenobiotic might consume so much ATP as to jeopardize cell viability, whereas UDPGA and PAPS can be depleted without killing cells. Second, phosphorylation of endogenous substrates, such as glucose, is a mechanism for trapping endogenous substrates inside a cell. This works because the plasma membrane of all cells is a barrier to the passage of polar compounds by virtue of its hydrophobic properties (lipid bilayer) and its general lack of transporters that efflux phosphorylated compounds out of the cell. The same is true for the phosphorylated metabolites of zidovudine and related antiviral drugs; they are retained inside the cell that forms them. A lipid bilayer is also a physical barrier to other water-soluble conjugates, such as glucuronides and sulfonates, but these are transported out of the cell by various transporters. Third, phosphorylation of both small molecules (such as inositol) and proteins (such as membrane-bound receptors and various transcription factors) plays an important role in intracellular and intranuclear signaling. It is possible that some xenobiotics, if they were phosphorylated, might interfere with these regulatory systems and thereby disrupt cellular homeostasis. Fourth, even if xenobiotics were phosphorylated in the liver and excreted in bile, they would be rapidly hydrolyzed by high levels of alkaline phosphatase lining the surface of enterocytes in the small intestine, which would promote reabsorption of the xenobiotic (by the very process exploited in the design of phosphorylated prodrugs such as fosamprenavir). Whatever the reason, there appears to be strong evolutionary pressure against the conjugation of xenobiotics with phosphoric acid.

INTRODUCTION

Toxicokinetics refers to the quantitative study of absorption, distribution, metabolism, and excretion (ADME) of chemicals in biota through measurement and modeling of their concentrations or amounts in biological matrices (e.g., blood, plasma, excreta, exhaled air, tissues) as a function of time. Experimental studies of toxicokinetics facilitate the characterization of the temporal profile of the concentration of chemicals and their metabolites in the target tissue or other biological matrices, reflective of the net effect of the rate and extent of absorption through one or more exposure routes, distribution to tissues and organs via systemic circulation as well as disposition by metabolism and excretion (Fig. 7-1). The experimental and quantitative approaches used today for characterizing toxicokinetics of xenobiotics were derived from such studies extensively conducted with drugs over the past decades (traditionally known as pharmacokinetics) (Gibaldi and Perrier, 1975, 1982; O'Flaherty, 1981; WHO, 1986; Rescigno, 1997; Tozer and Rowland, 2006). Toxicokinetic data and analyses constitute an essential part of systematic approaches to safety/risk evaluation of xenobiotics and other substances including therapeutic drugs.

A fundamental goal of toxicokinetics is to facilitate the determination of dose delivered to the organism in view of understanding systemic exposure to the toxicant. For a scientifically sound interpretation of toxicology studies and characterization of dose–response relationships, it is preferable to relate adverse responses to the dose delivered to the target organ (or to systemic circulation) in the form of

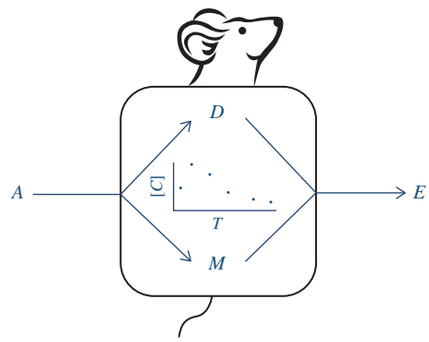

Figure 7-1. *Illustration of the key processes determining the time course of the concentration ([C] vs. T) of a toxic chemical in the target site (A: absorption from the dosing solution or the exposure medium; D: distribution in the blood stream and tissues; M: metabolism by hepatic and extrahepatic tissues; E: excretion).*

putative toxic moiety. In fact, the relationship between administered dose and adverse responses is better understood when the toxicokinetic data or models are used to translate the administered dose in terms of a relevant measure of internal dose (i.e., dose metrics) (U.S. EPA, 2006, 2014). Consistent with the current understanding of the mode of action of a particular chemical, the dose metrics reflect the intensity and level of a toxicologically active form of the chemical in the target or surrogate compartment during a specific period

Table 7-1

Considerations for Selecting a Dose Metric of Relevance to the Mode of Action of a Chemical

ASPECT	EXAMPLE
Intensity	Peak, average, or integral
Level	Concentration, amount, or rate of production
Moiety	Parent chemical, metabolites, or adducts
Time window	Instantaneous, daily, lifetime, or specific lifestage
Matrix	Blood, plasma, or target tissue (e.g., brain)

(Table 7-1). In this regard, the maximal blood concentration (C_{max}), the area under the blood concentration versus time curve (AUC) and the amount metabolized are the common dose metrics used in interpreting toxicity data. Fig. 7-2A presents a time course of the blood concentration of a chemical following its administration via the oral route. The C_{max} and AUC can be obtained following such time-course measurements of chemical concentrations in plasma, blood, or tissues in toxicokinetic studies. However, due to ethical and feasibility considerations, toxicokinetic data cannot always be obtained for all biological matrices, dose levels, time frames, exposure routes, and scenarios of interest in test animals and humans. Therefore, a pragmatic and scientifically sound approach would be to use the available toxicokinetic data to conduct a non-compartmental analysis or to develop mathematical models that may be empirical or mechanistic in nature. The models in toxicokinetics range from a simple, one-compartment model to complex multicompartment models, with some of them explicitly incorporating mechanistic determinants of chemical uptake, distribution, and disposition (O'Flaherty, 1981; Gibaldi and Perrier, 1982; Tozer and Rowland, 2006).

This chapter begins with an introduction to toxicokinetic data and concepts, followed by the fundamentals of classic and physiologic toxicokinetic models, as well as their applications in toxicology, risk assessment, and biomonitoring.

TOXICOKINETIC DATA

The interest in toxicokinetics arises from the need to interpret toxicity and biomonitoring studies on the basis of how much of a chemical was absorbed, biotransformed, and distributed to the target site or excreted out of the body at various time periods. The use of data on the fraction of the dose absorbed represents one level of refinement in relating to the onset and progression of adverse responses in a toxicology study. A more refined strategy would be to examine the internal dose of relevance to the mode of action of the chemical (e.g., maximal, average, or integrated concentration of the unbound chemical or its toxic metabolite in blood or tissue during a specific timeframe). In this regard, the whole blood and plasma are convenient sampling matrices that also reflect the net impact of ADME processes in the organism. Furthermore, these biological matrices, in many cases, can effectively reflect the extent of target tissue exposure as the cellular matrix equilibrates with the free chemical in the extracellular fluid. The C_{max} and AUC are the two dose metrics frequently obtained from quantification of chemical concentrations in whole blood or plasma samples in toxicokinetic studies.

Fig. 7-2A presents the blood kinetic data collected in a group of animals as part of the toxicological evaluation of a xenobiotic following a single oral dose of 100 mg/kg body weight. The toxicokinetic curve indicates an initial phase of increasing concentration determined by the rate of absorption, then a peak or plateau during which absorption rate equals elimination rate, followed by a phase dominated essentially by elimination. In this hypothetical example, the mean blood concentration of the parent chemical in the treatment group corresponded to 0, 1.32, 2.74, 3.37, 3.55, 2.89, 1.67, and 0.37 mg/L at pre-exposure, or at 2, 4, 6, 8, 10, 12, and 24 hours post-exposure, respectively. The $C_{max,blood}$ is 3.55 mg/L for this treatment group. Regarding AUC_{blood}, a common method of calculation involves summing the areas of trapezoids constituting the time-course curve (Gibaldi and Perrier, 1982; WHO, 1986). The trapezoidal method involves (i) averaging the blood concentrations found at two consecutive sampling times and (ii) multiplying it with the time interval between the two sampling periods (Figs. 7-2B and 7-2C). The lower panel in Fig. 7-2C illustrates the calculation of AUC for one trapezoid (4.56 (mg/L)·h), using the mean blood concentrations of 2.89 and 1.67 mg/L obtained at 10 and 12 hours post-dosing. For this particular dataset, AUC_{0-24h} (= 41.65 (mg/L)·h) corresponds to the sum of areas of the seven trapezoids, that is, 1.32, 4.06, 6.11, 6.92, 6.44, 4.56, and 12.24 (mg/L)·h. For determining the AUC until complete elimination of the substance (i.e., 24 hours to infinity), the area of the last trapezoid is additionally computed by dividing the last measured blood concentration by the rate of elimination (AUC_{last}/K_{el} where K_{el} = first-order elimination rate constant, h^{-1}). The trapezoidal rule can also be used to calculate the area under the first moment curve (i.e., [concentration × time] vs. [time]). In turn, the ratio of the area under the first moment curve (AUMC) to the AUC is indicative of the mean residence time (MRT), that is, the average time spent by drug or chemical molecules in the body (Rowland and Tozer, 2011).

The timing of sample collection and the time intervals between samples in toxicokinetic studies should be appropriate to enable reliable calculation of the dose metrics of interest. The time-course data collected should (i) capture the critical kinetic phases in the exposed animals, (ii) allow the estimation of fundamental toxicokinetic parameters, and (iii) permit, to the extent possible, the characterization of C_{max} and AUC. In practice, at least two time points are chosen for sampling in the early phase to characterize absorption and distribution phases, and at least three time points are chosen for sampling during the terminal elimination phase, with the collected samples representing change in concentration by at least a factor of two or preferably by an order of magnitude. Chemical-specific toxicokinetic properties, limit of detection of the analytical method along with statistical considerations can facilitate the determination of the number of samples, sampling time intervals, and volume of biological samples to be collected. The number and volume of samples drawn should be such that they do not compromise the normal physiological status of the animal (e.g., not drawing more than 10% of the blood volume during the AUC sampling interval (Cayen, 1995).

The accuracy of calculated dose metrics depends upon the number of data points collected in a toxicokinetic study whereas their magnitude depends upon the dose administered, exposure route, scenario (single or multiple doses), as well as the rates and extent of ADME influenced by factors such as age and pathophysiological state of the test subject or animal. When all required time-course data are not available or could not be collected in an animal or a human study to facilitate confident calculation of AUC or another metric of internal dose, the limited available data are subject to analysis or modeling to derive useful toxicokinetic parameters to gain a better characterization of the time course of the chemical in the biota. The choice of analysis or modeling method depends upon the underlying question(s) of the toxicological evaluation, the richness of the available data sets (toxicology, mode of action, and toxicokinetics), as well as the precision and predictive ability required for the end-use. These approaches, enabling the understanding of the net impact of ADME processes on the time-course behavior of

xenobiotics, take into account the fundamental toxicokinetic concepts described below.

TOXICOKINETIC CONCEPTS

Absorption and Bioavailability

The rate and extent of absorption, or the entry of a chemical into the systemic circulation, depends upon the dose, exposure route, as well as the volume and type of exposure matrix or dosing vehicle. Whereas human exposure to environmental chemicals occurs through the dermal, inhalation, and oral routes, laboratory animal experiments might additionally involve administrations by the intravenous (IV), intraperitoneal (IP), or intramuscular (IM) routes (Turner et al., 2011). The rate and efficiency with which a given chemical crosses the biological membrane barrier determine how quickly and how much of it appears in the systemic circulation. Whereas absorption might be incomplete when exposure occurs via extravascular routes, the intravenous dosing assures full (100%) delivery of the dose into the systemic circulation, and can therefore be used effectively as a benchmark of absorption by non-IV routes. The extent of absorption of a toxicant can be experimentally determined by comparing the time course of plasma toxicant concentration after IV and extravascular dosing. The AUC associated with the extravascular dose in reference to the AUC for the intravenous route is called *bioavailability* (F). In single-dose toxicokinetic studies, F is determined by using different IV and non-IV doses according to the following equation, provided the toxicant does not display dose-dependent or saturable kinetics:

$$F = \frac{(\text{AUC}_{\text{non-IV}} \,/\, \text{Dose}_{\text{non-IV}})}{(\text{AUC}_{\text{IV}} \,/\, \text{Dose}_{\text{IV}})}, \tag{7-1}$$

where $\text{AUC}_{\text{non-IV}}$, AUC_{IV}, $\text{Dose}_{\text{non-IV}}$, and Dose_{IV} are the respective areas under the blood concentration versus time curves and doses for non-IV and IV administrations. Conceptually, the F value for a non-IV route (e.g., oral) would range between 0 and 1, with the value closer to 1 indicating better absorption and systemic availability of a chemical by that particular route of exposure. When $F < 1$, it indicates that less than 100% of the administered dose is able to reach the systemic circulation. For example, the systemic availability of an orally administered toxicant is governed by its absorption at the gastrointestinal barrier, metabolism within the intestinal mucosa, as well as metabolism and biliary excretion during its first passage through the liver. The chemical may be absorbed to a limited extent because of low aqueous solubility preventing its effective dissolution in the gastrointestinal fluid or low permeability across the brush-border membrane of the intestinal mucosa. Extensive degradation by metabolic enzymes residing at the intestinal mucosa and the liver may also minimize entry of the chemical in its intact form into the systemic circulation. Metabolism and excretion of the toxicant at the intestinal mucosa and the liver prior to its entry into the systemic circulation is called presystemic extraction or first-pass effect. The following equation accounts for the action of absorption and sequential first-pass extraction at the intestinal mucosa and the liver as determinants of the bioavailability (F) of a toxicant taken orally:

$$F = f_g \cdot (1 - E_m) \cdot (1 - E_h), \tag{7-2}$$

where f_g is the fraction of the applied dose that is released and absorbed across the mucosal barrier along the entire length of the gut, E_m is the extent of loss due to metabolism within the gastrointestinal mucosa, and E_h is the loss due to metabolism or biliary excretion during first-pass through the liver.

While the *extent* of absorption is important for calculating the total amount of the administrated dose that actually crossed the biologically barrier(s) to reach systemic circulation and tissues, the *rate* of absorption is critical to understand the time course of the plasma, blood, or tissue concentration of a chemical following dosing. For the oral route, in simple cases, it can be computed as the first-order absorption rate constant (K_a, h^{-1}) times the amount available for

absorption (mg). For illustrative purpose, let's assume that a xenobiotic possesses a K_a value of 0.1 h^{-1}. It would imply that the same fraction of the amount in gut is absorbed per unit time, regardless of the administered dose. In this particular case, 9.5% of the dose is absorbed after 1 hour, even though the rate constant is 0.1 h^{-1} (or 10 percent per hour), because the amount remaining in the gut continuously decreases with time. If the amount absorbed per unit time is constant (e.g., 10 mg/h) regardless of the magnitude of the dose administered (1, 10, or 100 g), then it is said to follow zero-order process. Dietary exposure to chemicals is frequently described as a zero-order (or constant) input process, because it results in a fairly constant input dose to the exposed animals. The zero-order description is also used to reflect the capacity-limitation of a system (e.g., transport system), that is, to represent a system working at its maximal capacity but not functioning proportionally after a certain dose. The concepts of proportionality, capacity-limitation, and saturation are applicable to all phases of toxicokinetics and are critical in interpreting toxicity data.

The impact of the rate of absorption on the resulting plasma concentration profile of a chemical is illustrated in Fig. 7-3 using three different values of K_a. As shown in Fig. 7-3, slowing the absorption rate of a toxicant leads to a decrease in the C_{max} and a delay in time to reach C_{max} (T_p) while maintaining the same extent of absorption or bioavailability (compare case 2 to case 1). The converse is true, that is, accelerating rate of absorption increases C_{max} and shortens T_p. The dependence of T_p and C_{max} on absorption rate has obvious implication in the speed of onset and maximum toxic effects following exposure to a chemical. Case 3 in Fig. 7-3 illustrates the peculiar situation when the absorption rate is so much slower than the elimination rate. In this case, the terminal rate of decline in plasma concentration reflects the absorption rate constant, instead of the elimination rate constant; that is, the washout of toxicant is rate-limited by slow absorption until the applied dose is completely absorbed or removed, beyond which time the toxicant remaining in the body will be cleared according to the elimination rate constant. This means that continual absorption of a chemical can affect the persistence of the toxic effect following an acute exposure, and that it is important to institute decontamination procedure quickly after overdose or accidental exposure to a toxicant. This is especially a consideration in occupational exposure via dermal absorption following skin contact with permeable industrial chemicals.

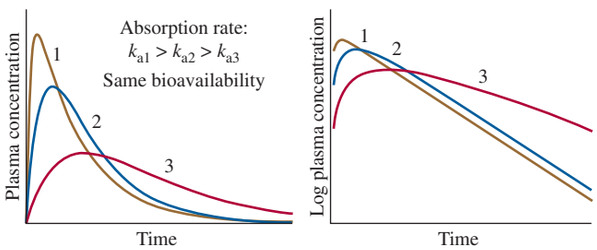

Figure 7-3. *Influence of absorption rate on the time to peak (T_p) and maximum plasma concentration (C_{max}) of a hypothetical toxicant.* The left panel illustrates the change in plasma concentration–time curves as the first-order absorption rate constant (k_a) decreases, while keeping the extent of absorption or bioavailability (F), hence the area-under-the-curve (AUC), constant. The right panel displays the same curves in a semilogarithmic plot. Time to peak plasma concentration shows a progressive delay as k_a decreases, along with a decrease in C_{max}. In cases 1 and 2, the terminal decline in plasma concentration is governed by elimination half-life; hence, the parallel decline in the semilogarithmic plot. In case 3, the absorption becomes so slow that decline in plasma concentration in the terminal phase reflects the absorption half-life, that is, washout of toxicant is rate-limited by absorption. Accordingly, the terminal decline is slower than in cases 1 and 2.

Volume of Distribution

The volume of distribution, V_d, corresponds to the apparent volume of a biological fluid in which a xenobiotic is diluted, and is expressed in units of volume (mL or L of blood, plasma, or plasma water). V_d would be approximately equal to the volume of blood if the chemical resided solely in blood and distributed uniformly among the blood components (plasma, erythrocytes). Hydrophilic substances exhibit smaller volumes of distribution, often close to 0.6 L/kg (or 60% of body weight) in adults, approximating the total body water in plasma (4%), interstitial fluid (21%), and intracellular fluid (35%). Those substances that are highly bound to plasma proteins and not showing any permeation in the blood capillaries or tissue membranes would result in V_d reflective of the extracellular fluid. Xenobiotics exhibiting a marked affinity for tissue or fat depots have large V_d (exceeding physiological fluid spaces and body weight) leading to low plasma concentrations. The mechanisms of tissue sequestration not only include partitioning of a toxicant into tissue lipids, but also involve binding to tissue proteins, concentrative uptake by active transporters, and trapping in specialized organelles (e.g., pH trapping of amine compounds in acidic lysosomes) (Assmus et al., 2017). In the case of xenobiotics that are extremely lipophilic, their V_d can be approximated to the lipid content of the body. For example, the V_d of DDT is about 17.5 L lipid (i.e., 25% of body weight of 70 kg) (Kirman et al., 2011). Conversely, the V_d in terms of L of whole blood can be calculated with the knowledge of tissue:blood partition coefficient (P_{tb}, in units of L blood/L tissue). The P_{tb} values reflect the relative distribution of a chemical between tissues and blood, at equilibrium. For example, $P_{tb} = 1$ for a chemical indicates that its concentration will be the same in the tissue and blood at equilibrium, whereas a P_{tb} value of 50 of a chemical in non-metabolizing tissue indicates that the concentration of this chemical will be 50 times greater in that tissue compared to the blood concentration at equilibrium. The P_{tb} along with the corresponding tissue volumes determines the extent of dilution of a chemical in the body. Thus, the sum total of blood volume and tissue volumes (expressed as blood-equivalent volume, i.e., $P_{tb} \times V_t$) would correspond to the V_d of chemicals (Poulin and Theil, 2002, 2009; Rodgers and Rowland, 2007):

$$V_d = V_b + \sum (V_t \cdot P_{tb}), \tag{7-3}$$

where V_b and V_t refer to the volumes of blood and tissue, respectively.

For example, in the case of a chemical that is uniformly distributed in the body with a P_{tb} of 1 (i.e., the concentration in the blood and soft tissues are identical at equilibrium), the total volume of distribution would be equal to 244 mL in the rat (Fig. 7-4 left panel; blood volume of 15 mL plus tissue volume of 229 mL). However, when the P_{tb} of a chemical is greater than 1 (e.g., overall P_{tb} for the soft tissues = 6.77 for *n*-hexane), the apparent distribution volume is greater than the actual physical volume of the animal (Fig. 7-4 right panel; tissue volume × tissue:blood partition coefficient = 229 mL tissue × 6.77 mL blood/mL tissue = 1551 mL blood-equivalent volume plus blood volume of 15 mL for a total V_d of 1566 mL in the rat). Accordingly, for 1,1,1,2-tetrachloroethane, a chemical with P_{tb} values of 2.1, 51.5, and 0.95 for the richly perfused tissues, adipose tissue, and rest of body (Gargas et al., 1989; Andersen et al., 1991), the computed V_d in the rat would be 1.18 L (Table 7-2) even though its body weight (i.e., physical volume) is only 0.25 kg. While V_d for environmental chemicals are often reported in units of L blood (or L blood per kg body weight), the V_d values for drugs are reported in units of L plasma or L plasma water, with or without normalization to body weight. V_d in units of

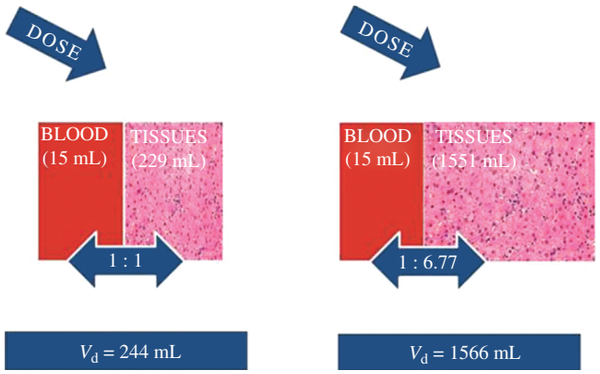

Figure 7-4. *Illustration of the physical and apparent volumes of distribution (V_d).* The left panel shows the physical volume of the rat corresponding to the sum of blood and tissue volumes in which a chemical is distributed equally throughout the body (V_d = 15 + 229 mL = 244 mL). The right panel shows the V_d for a lipophilic chemical equaling 1566 mL, as the sum of the volume of blood (15 mL) and the blood-equivalent volume of tissues calculated as the product of tissue:blood partition coefficient and the tissue volume (i.e., 6.77 × 229 mL = 1551 mL).

L of plasma is calculated by accounting for the interplay of binding to plasma and tissue proteins determining the free or unbound drug concentrations, as follows (Gibaldi and Perrier, 1982):

$$V_d = V_p + \sum\left(\frac{f_{up}}{f_{ut}}\right) \cdot V_t', \tag{7-4}$$

where f_{up} is the unbound and nonionized fraction of toxicant in plasma, f_{ut} is the effective unbound fraction in a tissue region, V_p corresponds to the volume of plasma, and V_t' represents the extravascular space plus erythrocyte volume. In this case, tissue:plasma partitioning is governed by the ratio f_{up}/f_{ut}. Thus, a drug that has high affinity for plasma proteins (e.g., albumin and/or α_1-acid glycoprotein) relative to tissue proteins has a restricted distribution volume; for example, the anticoagulant warfarin with a plasma-bound fraction of 0.995 or f_{up} of 0.005 (Table 7-3). On the contrary, a drug that has a high affinity for tissue proteins and lesser affinity for plasma proteins can have a very high V_d. For example, the tricyclic antidepressant nortriptyline has a good affinity for plasma proteins with a bound fraction of 0.92 or f_{up} of 0.08; however, binding of nortriptyline to tissues constituents is so much higher such that it has a V_d of 18 times the body weight in adult humans (Table 7-3).

Clearance

Clearance (CL) is the apparent volume of a physiological fluid (e.g., blood, plasma, plasma water) that is cleaned of the toxicant per unit time (i.e., mL/min or L/h). Thus, a CL value of 1 L blood/h is interpreted as 1 L of blood being completely cleared of a toxicant in systemic circulation per hour. Accordingly, high values of clearance indicate efficient and generally rapid removal of chemicals from the systemic circulation, whereas low clearance values indicate slow and less efficient removal of a toxicant from the body. A formal definition of total body clearance (CL_{total}) is the ratio of overall elimination rate of a toxicant divided by plasma concentration (i.e., amount eliminated per unit time/C_{plasma}); in effect then, CL_{total} expresses the overall efficiency of the elimination mechanisms operative in the body. Because this measure of elimination efficiency is with respect to blood or plasma toxicant concentration, it is also referred to as blood or plasma clearance.

CL_{total} of a xenobiotic equals the sum of all individual clearance processes occurring in parallel contributing to its removal from systemic circulation, as shown below (Gibaldi and Perrier, 1982; Rowland and Tozer, 2011):

$$CL_{total} = CL_{hepatic} + CL_{renal} + CL_{other}. \tag{7-5}$$

The integral measure of the blood concentration (AUC_0^∞) in relation to the systemic dose (i.e., $Dose_{IV}$, or Dose via extravascular routes adjusted for bioavailability) is useful in computing CL_{total} as follows:

$$CL_{total} = \frac{Dose_{iv}}{AUC_0^\infty} = \frac{F \cdot Dose_{oral}}{AUC_0^\infty}. \tag{7-6}$$

If the non-hepatic clearances are negligible for a chemical, then Eq. (7-5) becomes $CL_{total} = CL_{hepatic}$. Further, as per Eq. (7-6), the inverse relationship between CL and AUC would suggest that for a given dose, the chemical or the species with lower $CL_{hepatic}$ will exhibit higher AUC and hence greater systemic exposure to the parent chemical.

Quantitative descriptions of $CL_{hepatic}$ have been developed by accounting for hepatic blood flow, unbound fraction of chemical at the site of metabolism, and intrinsic metabolic clearance (Gibaldi and Perrier, 1982; Wilkinson, 1987; Rowland and Tozer, 2011). If delivery of the toxicant to its intracellular site of removal is rate-limited by liver blood flow (Q_h) and the toxicant is assumed to have equal, ready access to all the hepatocytes within the liver (i.e., the so-called well-stirred model), then $CL_{hepatic}$ (CL_h) becomes:

$$CL_h = Q_h \cdot E_h = \frac{Q_h \cdot f_{ub} \cdot CL_{int}}{f_{ub} \cdot CL_{int} + Q_h}, \quad (7\text{-}7)$$

where E_h is the hepatic extraction ratio (fraction of the amount of chemical entering the liver that is subjected to elimination by metabolism) and $f_{ub}{\cdot}CL_{int}$ is the hepatic intrinsic clearance that embodies a combination of factors that determine the access of the toxicant to the enzymatic sites (e.g., plasma protein binding and sinusoidal membrane transport) as well as the biochemical efficiency of the metabolizing enzymes (e.g., V_{max}/K_M for an enzyme obeying Michaelis kinetics). CL_{int} would also embody canalicular transport activity if the toxicant is subject to biliary excretion. Eq. (7-7) dictates that CL_h of a toxicant from the blood is bounded by either liver blood flow (Q_h) or intrinsic clearance (i.e., $f_{ub}{\cdot}CL_{int}$). Note that when $f_{ub}{\cdot}CL_{int}$ is very much higher than Q_h, the E_h approaches unity (i.e., near-complete or very high extraction during each passage of toxicant through the hepatic sinusoid) and CL_h approaches Q_h. For example, trichloroethylene exhibits a high CL_{int} value of 15.6 L/h and E_h of 0.92 in the rat (Table 7-4), implying that liver blood flow rather than enzyme content would be the limiting factor of its hepatic clearance. This reflects the fundamental notion that hepatic clearance of a xenobiotic cannot exceed the hepatic blood flow rate (0.004, 0.02, and 1.6 L/min in mice, rats, and humans, respectively) (Travis and Hattemer-Frey, 1991) even if the intrinsic rate of metabolism in the liver is greater than the rate of hepatic blood flow. At the other extreme, when $f_{ub}{\cdot}CL_{int}$ is very much lower than Q_h, the E_h becomes quite small (i.e., low extraction) such that CL_h nearly equals $f_{ub}{\cdot}CL_{int}$. In this instance, CL_h would be limited by the enzyme capacity and not chemical delivery to liver, that is, even if hepatic blood flow brings more chemical than the metabolic capacity of the organ, the metabolism will only occur at the relatively inefficient rate characterized by its CL_{int} (e.g., CL_{int} = 0.02 L/h and E_h = 0.02 for 1,1,1-trichloroethane) (Table 7-4). The extent of hepatic extraction of drugs and xenobiotics is generally referred to as low, medium, or high when the value of E_h is below 0.3, between 0.3 and 0.7, or above 0.7, respectively. The emerging literature supports that the E_h not only reflects hepatic metabolism associated with the unbound chemical but also the albumin-facilitated uptake of certain substances (Poulin et al., 2016, 2017; Fukuchi et al., 2017).

The renal clearance depends upon glomerular filtration, tubular reabsorption, and tubular secretion as follows (Kenakin, 2009):

$$CL_{renal} = f_{ub} \cdot (GFR + CL_{secretion}) \cdot (1 - F_{reabsorbed}) \quad (7\text{-}8)$$

where f_{ub} = unbound fraction of the chemical in systemic circulation, GFR = glomerular filtration rate, and $F_{reabsorbed}$ = fraction reabsorbed. Physiologically, the filtration clearance depends upon GFR (1.79 mL/(min·kg)) while $CL_{secretion}$ is limited by the renal blood flow [17.14 mL/(min·kg)] similar to hepatic clearance (Kunze et al., 2014). Renal clearance can also be calculated by dividing the total amount eliminated in urine by the AUC_{blood}, or alternatively by dividing the urinary excretion rate by the blood concentration.

The pulmonary clearance corresponding to the volume of physiological fluid (e.g., blood) cleared of a toxicant by exhalation is calculated as the alveolar ventilation rate divided by blood:air partition coefficient (P_b). Table 7-4 lists the P_b and the $CL_{pulmonary}$ for some environmental chemicals in the rat. Accordingly, chemicals with a low P_b (e.g., carbon tetrachloride = 4.52) show high $CL_{pulmonary}$ (= 1.19 L/h in the rat), whereas the reverse is true for chemicals with high P_b value (e.g., bromochloromethane with a P_b of 41.5 exhibiting $CL_{pulmonary}$ of 0.13 L/h). The CL and V_d of a substance together determine the elimination constant and half-life, as discussed below.

Elimination Half-life

Elimination rate constant (K_{el}) represents the fraction of the amount of chemical in body that is removed from systemic circulation per unit time. This is analogous to the fraction of the volume of distribution that is subject to elimination by various clearance mechanisms (i.e., CL/V_d). For example, if the CL = 10 L/h and V_d = 100 L, then the K_{el} equals 0.1 h^{-1} implying that 10% of the V_d will be cleared of the chemical per hour. However, the actual amount eliminated in 1 hour would be slightly less given that the amount in the body is declining continuously (from time zero to 1 hour). Thus, in the case of first-order elimination kinetics, the fractional elimination is constant but the amount eliminated is proportional to the amount remaining. For example, if the K_{el} equals 0.3 h^{-1}, the amount eliminated is less than 30% compared to the expectation based on the starting amount in the body (Table 7-5). Because the percent eliminated over a given time period remains constant regardless of the dose, it is more intuitive and convenient to refer to an elimination half-life ($t_{1/2}$), that is, the time taken for the concentration or amount of a chemical (in a biological matrix such as blood or body) to be reduced by half. Thus, after one elimination half-life, the initial blood concentration [C_0] would decline by 50%, that is, [C_0] × 0.5. After the second half-life, the remaining concentration would diminish by 50% due to elimination processes, that is, (0.5 × 0.5 × [C_0]) = 0.25 × [C_0], for a total decline of C_0 by a factor of 0.75 or 75%. After three, four, five, six, and seven half-lives, the initial concentration C_0 would diminish by 87.5%, 93.75%, 96.9%, 98.5%, and 99.2%, respectively. Elimination half-life, $t_{1/2}$, thus reflects the rapidity of disappearance of a toxicant following discontinuation of exposure and it depends upon both V_d and CL as shown below:

$$t_{1/2} = \frac{0.693 \cdot V_d}{CL}. \quad (7\text{-}9)$$

Table 7-5

Elimination of a Toxicant That Follows First-Order Kinetics ($K_{el} = 0.3\ h^{-1}$) by 1 Hour After IV Administration at Four Different Dose Levels

DOSE (mg)	TOXICANT REMAINING (mg)	TOXICANT ELIMINATED (mg)	TOXICANT ELIMINATED (% of dose)
10	7.4	2.6	26
30	22	8	26
90	67	23	26
250	185	65	26

The above relationship among $t_{1/2}$, V_d, and CL emphasizes that care should be exercised in interpretation of data when relying upon $t_{1/2}$ as the sole representation of elimination of a chemical in toxicokinetic studies, since $t_{1/2}$ is influenced by both the V_d for the toxicant and the rate at which it is cleared from the blood. For a fixed V_d, the $t_{1/2}$ decreases as CL increases because the chemical is being removed from this fixed volume at a faster pace as clearance increases. Conversely, as V_d increases, $t_{1/2}$ increases for a fixed CL because the volume of fluid that must be cleared of chemical increases but the efficiency of clearance does not. In this regard, highly lipophilic persistent organic chemicals exhibit a large V_d and low CL, and thus $t_{1/2}$ is in the order of several years in human adipose tissues (e.g., 2,2′,4,4′,5,5′-hexabromo diphenyl ether: 11.7 years, DDT: 4.2 years) (Geyer et al., 2004; Kirman et al., 2011). It is important to note that because $t_{1/2}$ is a function of CL and V_d of a chemical, it is not an independent toxicokinetic parameter.

The classic and physiologic models of the toxicokinetics of chemicals grounded on the concepts reviewed above (i.e., F, V_d, and CL) are described in the following sections.

CLASSIC TOXICOKINETIC MODELS

Model Structure

Classic toxicokinetics involves empirical analysis of the time-course data of a chemical and/or its metabolite(s) to derive parameters characteristic of their behavior in the exposed organism. This type of analysis uses one or more compartments to capture the toxicokinetics of a chemical in the organism (Fig. 7-5). The simplest structure of the classic toxicokinetic model represents the body as a homogeneous one-compartment system. When the log [C] versus time plot of the toxicokinetic data yields a curve as shown in Fig. 7-6 (top panel vs. bottom panel), it would indicate that differential distribution and equilibration processes among the model compartments need to be accounted for. In such cases, more than one compartment is chosen to adequately model the toxicokinetics of the substance (Figs. 7-6 and 7-7). Basically, in classical toxicokinetic analysis, whether the model structure corresponds to one, two, three, or more compartments is determined by the time-course data. Even though the number and nature of the compartments may not have exact anatomical or physiological correspondence, the resulting model structure and mathematical representation for a chemical would consistently fit with the available empirical data on the kinetics in one or more biological matrices such as whole blood, plasma, urine, exhaled breath, or tissues.

Mathematical Representation

In one-compartment toxicokinetic model reflecting homogeneous distribution of a chemical in the body, the rate of change in the amount ($d\text{Amount}_{body}/dt$, mg/h) equals the difference between the amount absorbed ($\text{Dose}_{absorbed}$) per unit time and amount eliminated from the body ($\text{Amount}_{eliminated}$) per unit time:

$$\frac{d\text{Amount}_{body}}{dt} = \frac{\text{Dose}_{absorbed}}{\text{h}} - \frac{\text{Amount}_{eliminated}}{\text{h}}. \quad (7\text{-}10)$$

Notationally,

$$\frac{dA_{body}}{dt} = K_a D - K_{el} A_{body}, \quad (7\text{-}11)$$

where A_{body} = amount in the body (mg), D = dose administered (mg), K_a = first-order absorption rate constant (h^{-1}), and K_{el} = first-order elimination rate constant (h^{-1}, equal to CL/V_d).

For the simple scenario of a single IV dose, because there is no absorption component, Eq. (7-11) reduces to the following form for describing change in chemical concentration in blood (C_b) due to first-order elimination:

$$\frac{dC_b}{dt} = -K_{el} C_b. \quad (7\text{-}12)$$

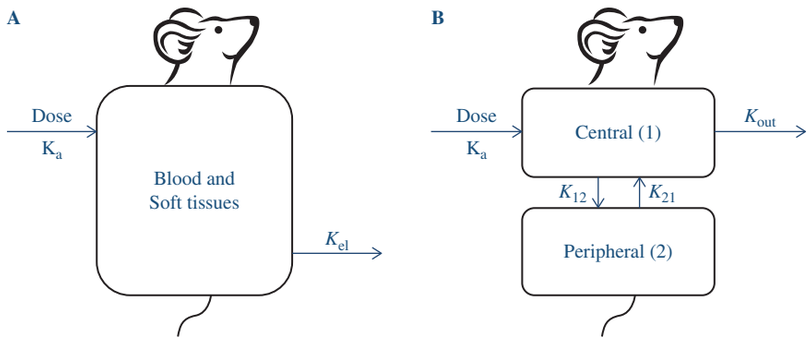

Figure 7-5. *Conceptual representations of compartmental toxicokinetic models.* Symbols for one-compartment model (**A**): K_a is the first-order absorption rate constant, and K_{el} is the first-order elimination rate constant. Symbols for two-compartment model (**B**): K_a is the first-order absorption rate constant into the central compartment (1), from the central compartment (1), K_{12} and K_{21} are the first-order rate constants for distribution between central (1) and peripheral (2) compartments whereas K_{out} is the first-order elimination rate constant from the central compartment.

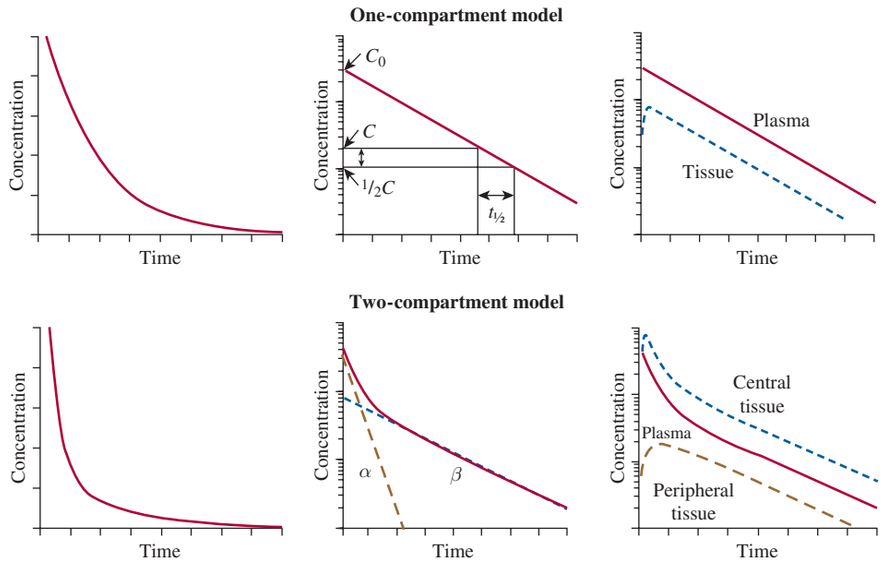

Figure 7-6. *Plasma concentration versus time curves of toxicants exhibiting kinetic behavior conforming to a one-compartment model (top row) and a two-compartment model (bottom row) following IV bolus injection. Left and middle panels show the plots on a rectilinear and semilogarithmic scale, respectively. Right panels illustrate the relationship between tissue (dash lines) and plasma (solid line) concentrations over time.* Note that tissue concentration can be higher, nearly the same, or lower than plasma concentration. Tissue concentration peaks almost immediately, and thereafter declines in parallel with plasma concentration. The right panel for the two-compartment model shows concentration–time profiles for typical tissues associated with the central (1) and peripheral (2) compartments as represented by short and long dash lines, respectively. For tissues associated with the central compartment, their concentrations decline in parallel with plasma. For tissues associated with peripheral compartment, toxicant concentration rises, while plasma concentration declines rapidly during the initial phase; it then reaches a peak and eventually declines in parallel with plasma in the terminal phase. Elimination rate constant K_{el} for one-compartment model and the terminal exponential rate constant β are determined from the slope of the log–linear concentration versus time curve. Half-life ($t_{1/2}$) is the time required for plasma toxicant concentration to decrease by one-half. C_0 is the concentration of a toxicant for a one-compartment model at $t = 0$ determined by extrapolating the log–linear concentration–time curve to the y-axis.

Upon integration based on the initial condition or time zero blood concentration ($C_{b,0}$), the equation to calculate chemical concentration in blood at any given time t ($C_{b,t}$) becomes:

$$\ln C_{b,t} - \ln C_{b,0} = -K_{el} \cdot t \tag{7-13}$$

or

$$C_{b,t} = C_{b,0} \cdot e^{-k_{el} \cdot t}. \tag{7-14}$$

Similarly, equations associated with a one-compartment model of single oral dose kinetics are presented in Table 7-6 (Gibaldi and Perrier, 1982).

When the toxicokinetic data indicate the existence of more than one characteristic tissue(s) or tissue group(s) with different equilibration and elimination profiles, a biexponential equation of the following form may be used to mathematically represent the kinetic behavior contained in the data:

$$C_t = A \cdot e^{-\alpha \cdot t} + B \cdot e^{-\beta \cdot t}, \tag{7-15}$$

where A and B are coefficients in units of toxicant concentration, α is the exponential constant for the distribution phase, and β is the exponential constant for the post-distribution or elimination phase.

In Eq. (7-15), the α constant corresponds to the slope of the residual log-linear plot and not the initial slope of the decline in

Table 7-6

Basic Equations of a One-Compartment Model for the Oral Route

DESCRIPTION	EQUATION
Rate of change in the amount of chemical in the body	$\frac{dA}{dt} = \text{In} - \text{Out}$
Rate of change expressed in terms of rates of absorption and elimination	$\frac{dA}{dt} = (K_a \cdot F \cdot D) - (K_{el} \cdot A_t)$
Concentration at any given time t (for $K_a > K_{el}$)	$C_t = \left(\frac{K_a \cdot F \cdot D}{V_d}\right)\left(\frac{e^{-K_{el}t}}{K_a - K_{el}}\right)$

Abbreviations: A, amount of chemical at any time t; C_t, concentration of chemical at any time t; D, oral dose administered; F, fraction of the oral dose absorbed; K_a, first-order absorption rate constant; K_{el}, first-order elimination constant; V_d, Volume of distribution.

the observed plasma toxicant concentration, that is, the initial rate of decline in plasma concentration approximates, but is not exactly equal to, the α rate constant (Fig. 7-6, bottom panel). It should be noted that distribution into and out of the tissues and elimination of the toxicant in the systemic circulation are occurring at all times, that is, elimination does occur during the "distribution" phase, and distribution between compartments is still ongoing during the "elimination" phase. As illustrated in Fig. 7-7, the dynamics of a bicompartment system is such that the governing factor, that is, be it intercompartmental distribution or elimination, for each of the phases depends on the relative magnitude of the rate constants for intercompartmental exchange and the elimination process. In the usual case, that of rapid distribution and relatively slow elimination (left panel of Fig. 7-7), the initial rapid phase indeed reflects extravascular distribution, and the later, slow phase reflects elimination after a dynamic equilibration between tissue and blood is attained. There are cases where distribution into some tissue group is much slower than elimination (right panel of Fig. 7-7). Then, the initial phase could largely reflect elimination, and the later phase is controlled by the slow redistribution of the toxicant from the tissues associated with the peripheral compartment to the central compartment, where it is eliminated (i.e., washout in the terminal phase is rate-limited by redistribution from the peripheral compartment).

The relative prominence of distributional phases in two-compartment models will often vary depending on the lipid solubility of the toxicant in each tissue grouping and any other sequestration and export mechanisms of a toxicant in particular tissues (e.g., tight binding to tissue proteins, active influx into or efflux out of the tissue cell types), as well as the competing influence of elimination from the visceral organs. For example, very rapid metabolism or excretion at the visceral organs would limit distribution into the slow or very slow tissue groupings. Also, there are times when equilibration rates of a toxicant into visceral organs overlaps with lean body tissues, such that the distribution kinetics of a toxicant into these two tissue groupings become indistinct with respect to the exponential decline of plasma concentration, in which case two instead of three tissue groupings may be observed. The concept of tissue groupings with respect to uptake or washout kinetics serves to justify the seemingly simplistic, yet pragmatic, mathematical description of extravascular distribution by the classic two- or three-compartment models.

Data Analysis and Parameter Estimation

Fig. 7-8A presents the toxicokinetic data, specifically blood concentration versus time, as measured in an experimental study following a single IV dose of 100 mg of a xenobiotic in the rat. Figs. 7-8B and 7-8C depict the same data following the application of $\log_{10}$ and natural log (ln) transformations. Given the behavior seen in these plots (i.e., a straight line in log transformed plots), a one-compartment model is fit to the concentration versus time-course data using Eq. (7-13). In this one-compartment model for a single IV dose, the initial concentration, C_0, corresponding to the

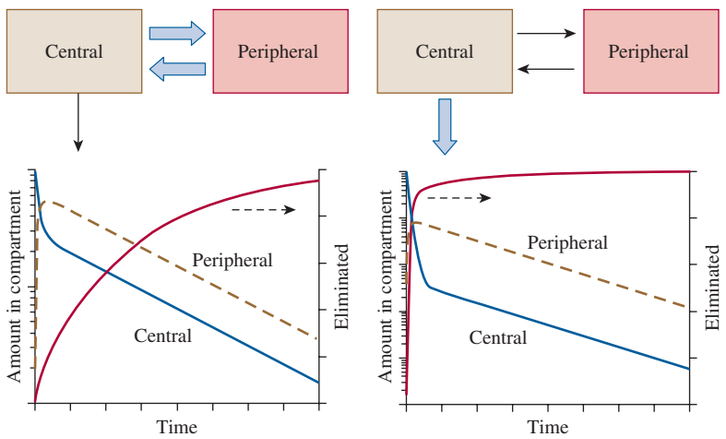

Figure 7-7. *Effects of interplay between kinetics of distribution and elimination processes on time course of exchange between peripheral (red) and central (blue) body compartments and removal from the body for toxicants whose disposition conforms to a two-compartment model.* Left panel depicts the more common scenario of rapid distribution between compartments relative to elimination, in which case elimination from the body occurs largely during the terminal phase when a dynamic equilibration between the central and peripheral compartment has been reached. Accordingly, half-life of the terminal phase is an appropriate measure of elimination. Right panel depicts the scenario of very slow distribution relative to elimination, in which case a substantial (>90% of dose) loss of toxicant occurs during the initial phase. The terminal phase reflects the slow redistribution of the toxicant sequestered in the peripheral site to the central site where it can be eliminated (i.e., washout is rate-limited by redistribution). Under this scenario, the initial phase reflects elimination kinetics, whereas the terminal phase reflects tissue distribution kinetics. (Adapted from Tozer and Rowland, 2006.)

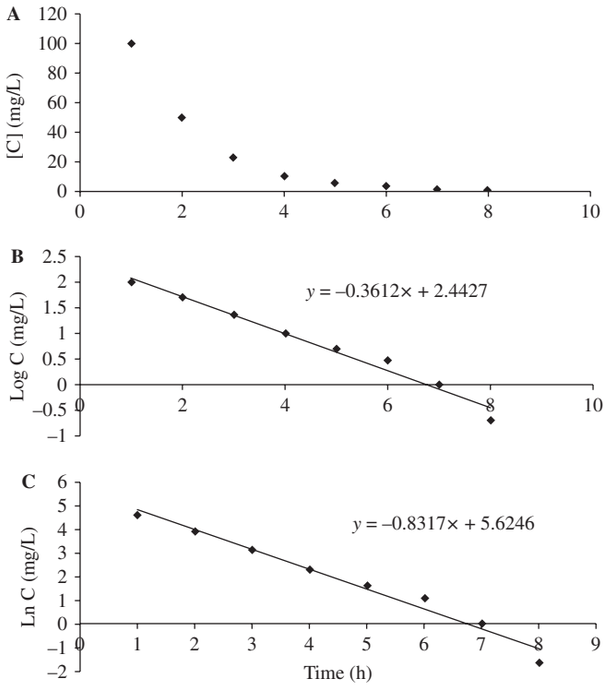

Figure 7-8. *Plots of the measured data (**A**) as well as the transformed data [log_{10} (**B**) and natural log (**C**)] on the blood concentration versus time following a single IV dose.*

intercept in Fig. 7-8C, equals the dose diluted in the apparent volume of distribution, V_d, as follows:

$$V_d = \frac{\text{Dose}}{C_0}. \tag{7-16}$$

Given that the dose in the present example equals 100 mg and the C_0 corresponding to the intercept is 5.62 (= 276 mg/L), the V_d equals 0.36 L. The K_{el} value equals the slope of the natural log transformation plot (Fig. 7-8C) corresponding to the concentration difference (i.e., ln C_t − ln C_0) over a time period (Δt). Thus, the K_{el} associated with this dataset equals 0.832 h^{-1} (Fig. 7-8C) or 0.3612 × 2.303 (Fig. 7-8B). The $t_{1/2}$ or the time taken for the initial concentration C_0 to become half its value (i.e., 0.5·C_0) can be calculated from the K_{el} value as follows:

$$t_{1/2} = \frac{\ln C_0 - (\ln C_0 + \ln 0.5)}{K_{el}} = \frac{0.693}{K_{el}}. \tag{7-17}$$

For the toxicant presented in Fig. 7-8, the $t_{1/2}$ value corresponds to 0.832 h. The toxicokinetic parameters discussed above, particularly K_{el} (or $t_{1/2}$) and V_d, can be used to calculate CL, which is an independent toxicokinetic determinant. For the chemical modeled after a single IV dose in Fig. 7-8, the CL equals 0.3 L/h (i.e., V_d of 0.36 L and K_{el} of 0.832 h^{-1}). The relationship among these parameters does not imply that CL is dependent on V_d or $t_{1/2}$; rather $t_{1/2}$ depends upon CL and V_d.

For a two-compartment model, CL is equal to V_d times β. In multicompartment models, V_d is calculated according to Eq. (7-18) based on the computation of area under the toxicant concentration–time curve:

$$V_d = \frac{\text{Dose}_{IV}}{\beta \cdot \text{AUC}_0^{\infty}}, \tag{7-18}$$

where Dose_{IV} is the IV dose or known amount of toxicant in the body at time zero, β is the elimination rate constant, and AUC_0^{∞} is the area under the toxicant concentration versus time curve from time zero to infinity. Because the concept of an overall apparent volume of distribution is strictly applicable to the terminal exponential phase, some investigators refer to it as V_β (for a two-compartment model) or V_z (for a general multicompartment model) (Gibaldi and Perrier, 1982). When Eq. (7-16), is applied to the situation of a multicompartment model, the resultant volume is the apparent volume of the central compartment and it corresponds to the proportionality constant relating the total amount of the toxicant in the central compartment to its concentration in plasma or whole blood.

When the empirical data on log [C] versus time exhibit behavior reflective of many compartments with differing characteristics, three, four, or more exponential terms may be required to obtain adequate fitting. Under these circumstances, the curve fitting can become a tedious exercise with the resulting model structure and parameters not being straightforward to interpret in physiological and biochemical terms. In such cases, it is preferable to opt for physiologically based models that can associate the observed kinetic behavior with identifiable compartments or tissues (e.g., liver, fat, kidney), as described in the next section.

PHYSIOLOGIC TOXICOKINETIC MODELS

The classic compartmental toxicokinetic models described in the previous section are developed by fitting empirical data on the concentration of parent chemical and/or metabolite(s) in the exposed organism. The parameter estimates obtained with these models are useful for toxicokinetic interpretations limited to the exposure duration, exposure route, dose levels, life stage, and species for which the experimental data were generated. In order to enhance the mechanistic basis of toxicokinetic analysis and to improve the application domain of the resulting parameter estimates, there is increasing interest in physiologically based pharmacokinetic (PBPK) models, also referred to as physiologically based toxicokinetic (PBTK) or biologically based biokinetic (BBBK) models.

The PBPK models describe the interrelationships among the key determinants of uptake and disposition to simulate the time-course behavior of xenobiotics and their metabolites in blood and various tissues. These models are essentially quantitative statements of the current state of knowledge concerning the mechanistic determinants of the toxicokinetics of a chemical in biota. The advantages of PBPK models in comparison with the classic compartmental models are that they permit: (i) the simulation of the concentration of chemicals and their metabolites not only in the blood but also in any other tissue of interest including the target organ, (ii) the evaluation of the nature and magnitude of the potential impact of physiological, physicochemical, and metabolic parameters on the toxicokinetics of chemicals, (iii) the prediction of the toxicokinetics of chemicals across species and populations using relevant input parameters, (iv) accounting for temporal change in physiological and metabolic parameters, complex dosing regimens, and saturable processes, and (v) the simulation of toxicokinetic datasets collected under various dosing situations (exposure routes, doses, and scenarios) with a single set of input parameters and equations. The impediments to the use of PBPK models relate to the fact that not only these models contain more parameters compared to the classic compartmental models but also the mathematics and programming required are not trivial. Furthermore, the range of values and distributions of input parameters are not always well defined for various chemicals and their metabolites in all species and pathophysiological states of interest. Nevertheless, PBPK models are conceptually

sound tools capable of providing insights into the toxicokinetics and tissue dose of toxicants beyond what classic compartmental models can provide because of the way in which they are constructed, parameterized, and implemented. The construction of the classic toxicokinetic model requires time-course data on the concentrations of chemicals in one or more biological matrices to begin with, whereas the PBPK modeling approach frequently uses a priori parameter estimates in mechanism-based equations to simulate the toxicokinetics of chemicals in biota. While the former approach determines the number, behavior, and volumes of the compartments based on the fitting exercise, the structure and complexity of a resulting PBPK model are determined by the critical determinants of toxicokinetics, available data sets, and intended end-use.

The practice of incorporating biological and physiological concepts into the analysis and interpretation of toxicokinetic data is not entirely new. The PBPK-type descriptions were developed for gaseous anesthetics as early as the 1920s and then applied to model the uptake and disposition of certain biopharmaceutics, antineoplastics, and volatile organic chemicals (Haggard, 1924; Teorell, 1937; Kety, 1951; Mapleson, 1963; Riggs, 1970; Bischoff et al., 1971; Dedrick et al., 1972; Fiserova-Bergerova, 1975). Since the publication of a PBPK for styrene by Ramsey and Andersen (1984), there has been increasing interest in the development of PBPK models for xenobiotics and drugs (Reddy et al., 2005; Krishnan and Andersen, 2010). Fig. 7-9 presents the key steps of PBPK modeling, with a specific end-use as the motivation for model development (e.g., chemical risk assessment) (WHO, 2010). Defining the scope and intended application of the PBPK model up-front is important to ensure that the model development process is concordant with the required level of precision and extent of evaluation. Overall, the construction of PBPK models begins with the development of a model structure, mathematical representation of key processes, and estimation of model parameters. The PBPK model equations and parameters are then written as a computer program, solved to provide toxicokinetic simulations, and compared with available data to guide further refinement or analysis (sensitivity, uncertainty, variability) in view of assessing the suitability of the model for the intended application.

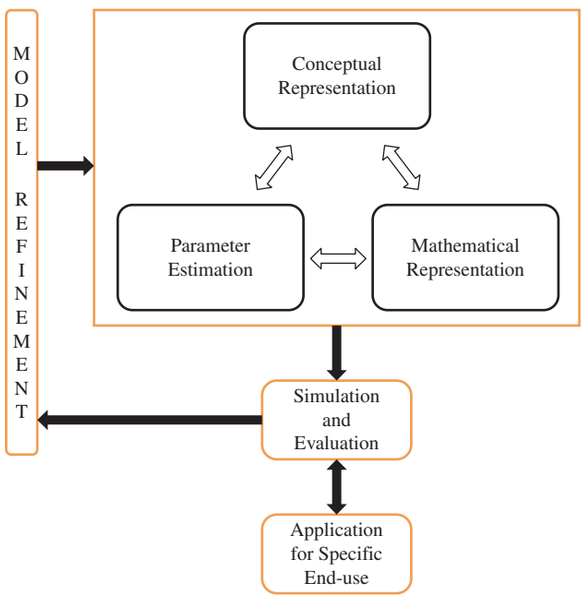

Figure 7-9. *Simplified schematic of the steps involved in the development of physiologically based toxicokinetic models.*

Model Structure

The structure of a PBPK model for a given chemical corresponds to a diagrammatic representation of key processes and pathways determining its toxicokinetics in the organism (i.e., species or individual). The PBPK model is represented as boxes and arrows, with the boxes corresponding to the organs (individual or groups) and the arrows reflecting the physiological flows and clearance processes. The art of developing a PBPK model structure requires striking a balance between the principles of parsimony (i.e., minimal but essential elements) and plausibility (i.e., reflective of physiological reality), while being consistent with the current state of knowledge on the toxicokinetics and mode of action of the chemical or drug under study. In other words, the complexity of PBPK models increases only when it is required to explain the behavior contained in the toxicokinetic data. In PBPK models, increments of complexity generally involve the addition of compartments with different time-constants (i.e., blood flow divided by the distribution volume specific to each tissue compartment) or mathematical representations of mechanisms to account for specific accumulation or disposition behavior of the chemical under study. The level of detail relates not only to the compartments (e.g., whole body, target tissue, or intracellular concentrations) but also to the chemical forms that are tracked within the model (e.g., parent chemical, metabolites, mixture components).

For a hydrophilic chemical whose concentrations across compartments are comparable, a one-compartment PBPK model might well be sufficient. However, for chemicals exhibiting different time-course profiles in various tissues, a multicompartmental PBPK description is required. Fig. 7-10 shows the structure of a four-compartmental PBPK model used for simulating the inhalation toxicokinetics of toluene, a lipophilic volatile organic chemical. In this particular case, the model compartments together represent ≈ 91% of body mass in adult rats. The remaining 9% (corresponding to the mass of the skeletal/structural components) is not included in the PBPK model because toluene does not exhibit significant affinity for, or accumulate in, skeletal and structural components. In this particular model, the "lung" compartment only represents the portal of entry, assuming no significant pulmonary metabolic activity toward toluene. The four compartments of this model corresponding to liver, fat, poorly perfused tissues, and richly perfused

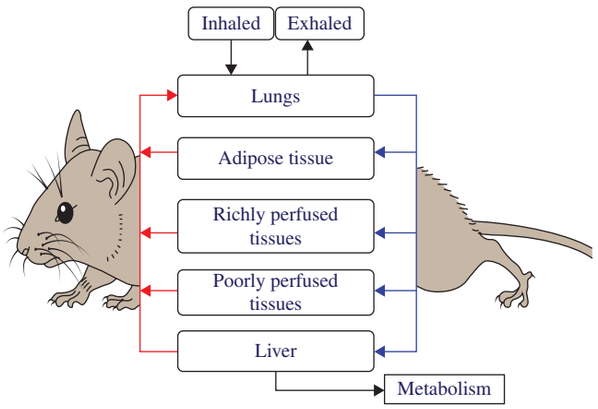

Figure 7-10. *Physiologically based toxicokinetic model for toluene, a low-molecular-weight volatile organic chemical.* The main route of its intake is via inhalation and absorption by the lungs. Transport of chemical throughout the body by blood is depicted by the arrows. Elimination of toluene as depicted by the model includes metabolism and exhalation. All compartments are perfusion-limited.

tissues together account for the mass balance of toluene entering the body and the mass balance of physiological flows in the model at any given time. The "fat" compartment in the PBPK model represents the adipose tissues in the body representing storage depot for toluene. The richly perfused tissue compartment comprises tissues such as adrenal, kidney, thyroid, brain, lung, heart, and testis whereas the poorly perfused tissue compartment represents muscle and skin, characterized by differences in the blood flow rate per gram tissue (Table 7-7). Whereas lumping of various tissues into a single compartment is ideal when the concentration versus time profiles is similar across the tissues, the splitting of compartments into component tissues are done often because of the need to simulate chemical concentrations in (i) target organ(s), (ii) organs with significant metabolism, binding, and excretion processes, (iii) sites with specific affinity or capacity for accumulation of the chemical under study (e.g., teeth, bone, fat), (iv) portals of entry into the body, or (v) those tissues that exhibit significant difference in time-constants due to physical activity or pathophysiological states.

Mathematical Representation

The fundamental equations used for characterizing xenobiotic concentrations in tissue compartments of PBPK models are given in Table 7-8. The following paragraphs provide sample descriptions of the computation of concentrations of neutral, nonionized chemicals in metabolizing and non-metabolizing organs as well as in systemic circulation (Himmelstein and Lutz, 1979; Gerlowski and Jain, 1983; Ramsey and Andersen, 1984; Rowland, 1985).

Computing Tissue Concentrations The rate of change in the amount of chemical in the tissue compartments (dA/dt) is proportional to the concentration difference ($C_{in} - C_{out}$) and the membrane permeability coefficient (k), as per Fick's first law as described below:

$$\frac{dA}{dt} = k \cdot (C_{in} - C_{out}). \tag{7-19}$$

Because the chemical input to the tissue (amount per unit time) equals the influx clearance (CL_{in}) times incoming concentration (C_{in}), whereas the chemical removal (amount per unit time) equals efflux clearance (CL_{out}) and the concentration leaving the compartment (C_{out}), the above mass balance differential equation (MBDE) can be rewritten as follows:

$$\frac{dA}{dt} = (CL_{in} \cdot C_{in}) - (CL_{out} \cdot C_{out}). \tag{7-20}$$

The concentration of free chemical leaving a tissue compartment, C_{out}, depends upon the amount of chemical in that particular compartment (A_t) and its distribution volume (i.e., tissue volume, V_t multiplied by tissue:blood partition coefficient, P_{tb}), such that the above equation becomes:

$$\frac{dA}{dt} = (CL_{in} \cdot C_{in}) - \left(CL_{out} \cdot \frac{A_t}{V_t \cdot P_{tb}}\right). \tag{7-21}$$

The clearance terms in the above equation depend upon the membrane permeability and tissue blood flow. Quantitatively, the influx

Table 7-8

Equations for Calculating the Rate of Change, Amount, and Concentration of Chemical in a Flow-Limited Compartment of a Physiologic Toxicological Model

DESCRIPTION OF THE EQUATION	MATHEMATICAL FORM
Rate of change in amount of chemical in tissue = Tissue blood flow rate × [Concentration in arterial blood – Concentration in venous blood leaving tissue]	$\frac{dA_{tissue}}{dt} = Q_{tissue} \times (C_a - C_{vt})$
Amount of chemical in tissue = [Rate of change in amount in tissue × Integration time interval] + Previous amount in tissue	$A_{tissue} = \left[\frac{dA_{tissue}}{dt} \times dt\right] + A_{tissue,t-1}$
Concentration of chemical in tissue = Amount in tissue/Tissue volume	$C_{tissue} = \frac{A_{tissue}}{V_{tissue}}$
Chemical concentration in venous blood leaving tissue = Concentration in tissue/Tissue:blood partition coefficient	$C_{vt} = \frac{C_{tissue}}{P_{tissue:blood}}$

Abbreviations: C_{tissue}, *concentration in tissue (mg/liter or mmol/liter);* Q_{tissue}, *blood flow rate (liters·h*$^{-1}$*);* V_{tissue}, *tissue volume (liters);* $P_{tissue:blood}$, *tissue:blood partition coefficient;* A_{tissue}, *amount in tissue (mg);* t, *current time;* $t-1$, *previous simulation time;* C_a, *arterial blood concentration;* C_{vt}, *venous blood leaving tissue.*
SOURCE: Based on Ramsey and Andersen (1984).

and efflux clearances can be expressed in terms of permeation area cross product (PA) and tissue blood flow rate (Q_t) as follows: PA $\times$ Q_t/(PA + Q_t). Accordingly, when the PA of a chemical is very large compared to Q_t, the latter becomes the limiting factor such that influx and efflux clearance values are equal to Q_t. In contrast, when PA << Q_t (i.e., membrane diffusion limiting the chemical movement into and out of a tissue compartment), then influx and efflux clearance values would equal PA (Gerlowski and Jain, 1983). In this regard, for small molecular weight compounds, blood flow rather than the membrane diffusion is the limited factor, such that the above MBDE can be rewritten as follows (Ramsey and Andersen, 1984):

$$\frac{dA}{dt} = Q_t(C_a - C_{vt}), \tag{7-22}$$

where C_a = concentration of chemicals in arterial blood entering the tissue compartment and C_{vt} = concentration of chemical in venous blood leaving the tissue

For high-molecular-weight compounds, the membrane diffusion rather than tissue blood flow is the limiting factor such that their flux through the cellular matrix and tissue blood needs to be accounted for separately (Table 7-9). If the diffusion of a chemical from tissue blood to cellular matrix is slow with respect to tissue blood flow, then both the extracellular and intracellular components are characterized (Fig. 7-11 and 7-12). However, when the tissue perfusion rate (i.e., blood flow) is very small compared to membrane diffusion, then the tissues are described as homogeneous, well-mixed compartments. Consequently, the rate of change in the amount of chemical in the tissue is described with a single equation for the whole tissue mass (Eq. 7-22), followed by the use of the output of this equation to calculate concentration in the tissue and venous blood leaving the tissue (Table 7-8).

For compartments exhibiting metabolic capacity, the rate of the amount cleared by metabolism (dA_{met}/dt) is also included such that the MBDE becomes:

$$\frac{dA}{dt} = Q_t(C_a - C_{vt}) - \frac{dA_{met}}{dt}. \tag{7-23}$$

The rate of metabolism in PBPK models is described as a first-order, second-order, or saturable process (Table 7-10). When the amount metabolized per unit time is directly proportional to the input variable (e.g., free concentration of chemical in liver), metabolism is described as a first-order process. The second-order equation is employed when the rate of metabolism depends on the available concentration of both the cofactor and the chemical. The saturable metabolism, often described as a Michaelis–Menten reaction, reflects first-order behavior at very low substrate concentrations and zero-order behavior at concentrations that are far excessive of the Michaelis parameter, K_m. All the metabolism descriptions presented in Table 7-10 are based on venous blood concentration (i.e., free concentration) of a xenobiotic, reflecting the "venous equilibration model" descriptions. Because the calculation of the rate of metabolism is integrated within Eq. (7-23), the blood flow limitation (i.e., perfusion limitation) of hepatic metabolism

Table 7-9

Equations Used for Describing Diffusion-Limited Uptake in Physiologic Toxicokinetic Models

SUBCOMPARTMENTS	EQUATIONS
Tissue blood	$\frac{dA_1}{dt} = Q_t \times (C_{in} - C_{out}) - [PA] \times (C_1 - C_2)$
Cellular matrix	$\frac{dA_2}{dt} = [PA] \times (C_1 - C_2)$

Abbreviations: C, concentration (mg/liter or mmol/liter); Q, flow rate (liters.h^{-1}); V, volume (liters); A, amount (mg); PA, permeability-area coefficient; C_1–C_2, concentration differential between tissue blood and cellular matrix.

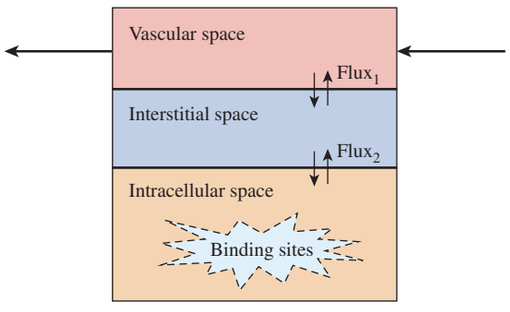

Figure 7-11. *Schematic representation of a lumped tissue compartment in a physiologically based toxicokinetic model.* The blood capillary and cell barriers separating the vascular, interstitial, and intracellular subcompartments are depicted in heavy black lines. The vascular and interstitial subcompartments are often combined into a single extracellular subcompartment.

Examples of Equations Used for Calculating the Rate of the Amount of Chemical Metabolized (dA_{met}/dt) in Physiologic Toxicokinetic Models

REACTION TYPE	EQUATION
First-order process	$\frac{dA_{met}}{dt} = K_f \cdot C_{vt} \cdot V_t$
Second-order process	$\frac{dA_{met}}{dt} = K_s \cdot C_{vt} \cdot V_t \cdot C_{cf}$
Saturable process	$\frac{dA_{met}}{dt} = \frac{V_{max} \cdot C_{vt}}{K_m + C_{vt}}$

Abbreviations: C_{cf}, concentration of the cofactor; C_{vt}, concentration of chemical in venous blood leaving the tissue; K_f, first-order reaction rate; K_m, Michaelis constant; K_s, second-order reaction rate constant; V_{max}, maximal velocity; V_t, volume of metabolizing tissue.

is automatically accounted for. Alternatively, the blood flow to liver and hepatic extraction ratio can be used explicitly to describe metabolism in PBPK models (as $Q_h \cdot E_h \cdot C_a$, where Q_h = liver blood flow rate, E_h = hepatic extraction ratio, and C_a = arterial blood concentration), but the E_h may be dose-dependent when saturation occurs in the dose range of interest.

Analogous to the hepatic clearance, the MBDE can accommodate biliary and fecal clearances by taking into account the rate of bile flow, the rate of transfer into and reabsorption from the bile, as per the molecular weight of the chemical or its conjugated metabolite. Urinary excretion is modeled as a function of the rates of filtration, reabsorption, and secretion (Eq. 7-8). The amount of chemical filtered (dF/dt) and the rate of change in the concentration of chemical or its metabolite in the urine (dU/dt) are calculated as follows:

$$\frac{dF}{dt} = \text{GFR} \cdot C_v, \tag{7-24}$$

$$\frac{dU}{dt} = U_o \cdot C_u, \tag{7-25}$$

where GFR = glomerular filtration rate, U_o = urinary output per unit time, C_v = unbound blood concentration of xenobiotic, and C_u = xenobiotic concentration in urine. The amount of chemical secreted (or reabsorbed) then equals the difference between the amount in urine and the amount filtered (Eq. 7-8).

Computing Blood Concentrations The rate of change in the amount of chemical in blood compartment in PBPK models can be calculated conceptually as per Eq. (7-22). Alternatively, the mass conservation equations can be solved to compute blood concentrations, as done for volatile organic chemicals (Ramsey and Andersen, 1984). In this regard, chemical input to the lung compartment equals the amount inhaled ($Q_p \times C_{inh}$) plus the amount returning to lungs via mixed venous blood ($Q_c \times C_v$), whereas the output equals the amount leaving the lungs via arterial blood ($Q_c \times C_a$) plus the amount exhaled ($Q_p \times C_{alv}$), as depicted in Fig. 7-13. Notationally,

$$Q_p C_{inh} + Q_c C_v = Q_c C_a + Q_p C_{alv}, \tag{7-26}$$

where C_{inh} = inhaled concentration, C_v = mixed venous blood concentration, C_a = arterial concentration, C_{alv} = alveolar concentration, Q_p = alveolar ventilation rate, and Q_c = cardiac output.

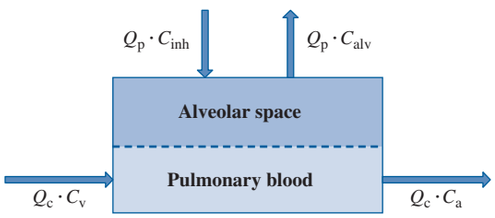

Figure 7-13. *Simple model for exchange of nonreactive volatile organic chemicals in the alveolar region of the respiratory tract.* Rapid exchange of toxicants in the simplified lung compartment between the alveolar gas (*blue*) and the pulmonary blood (*light blue*) maintains an equilibrium between them as symbolized by the dashed line. $\boldsymbol{Q_p}$ is alveolar ventilation (L/h); $\boldsymbol{Q_c}$ is cardiac output (L/h); $\boldsymbol{C_{inh}}$ is inhaled vapor concentration (mg/L); $\boldsymbol{C_a}$ is concentration of chemical in the arterial blood; $\boldsymbol{C_v}$ is concentration of chemical in the mixed venous blood. The equilibrium relationship between the chemical in the alveolar air ($\boldsymbol{C_{alv}}$) and the chemical in the arterial blood ($\boldsymbol{C_a}$) is determined by the blood:air partition coefficient $\boldsymbol{P_b}$, that is, $\boldsymbol{C_{alv}} = \boldsymbol{C_a}/\boldsymbol{P_b}$. (Based on Ramsey and Andersen, 1984.)

Given that lung equilibrates vapor between alveolar air and blood ($C_{alv} = C_a/P_b$), the above equation can be rewritten to compute arterial blood concentration as follows (Ramsey and Andersen, 1984):

$$C_a = \frac{Q_p C_{inh} + Q_c C_v}{\left(Q_c + \dfrac{Q_p}{P_b}\right)}. \tag{7-27}$$

The above equation simplifies to $C_a = C_v$ for highly nonvolatile chemicals (with a negligible value of C_{inh} and very large P_b) not metabolized in the lung compartment. In such situations, the conducting airways (i.e., nasal passages, larynx, trachea, bronchi, and bronchioles) are considered as inert tubes that carry the chemical to the pulmonary region, where diffusion occurs. When simple continuous ventilation-equilibration models are insufficient to describe the uptake behavior (e.g., regional uptake of highly soluble polar solvents), the adsorption and/or dissolution in the surface of the respiratory epithelium during inhalation as well as desorption during exhalation are taken into account along with the cyclic nature of respiratory exchange (Johanson, 1991).

The mixed venous blood concentration, C_v, entering the lung compartment results from the venous concentration of chemicals leaving the various tissue compartments following their equilibration as a function of the tissue:blood partition coefficients. The C_v is not a simple average of C_{vt} of the tissue compartments, as the fraction of cardiac output flowing into and out of the tissues is not identical across the compartments. Considering the fractional flow through the various compartments in the rat (e.g., liver = 0.25, fat = 0.09, slowly perfused tissues = 0.15, and richly perfused tissues = 0.51 [Tardif et al., 1997]), the C_v is calculated as the weighted average concentration as follows:

$$C_v = (0.25 \cdot C_{vl}) + (0.09 \cdot C_{vf}) + (0.15 \cdot C_{vs}) + (0.51 \cdot C_{vr}), \tag{7-28}$$

where subscripts vl, vf, vs, and vr correspond to venous blood leaving the liver, fat, slowly perfused tissue, and richly perfused tissue compartments.

Parameters: Significance and Estimation

The equations of the PBPK models contain a number of input parameters, which are conveniently grouped as physiological, physicochemical, or biochemical parameters including rate constants of reactions and clearance processes relevant to the chemical being modeled.

Physiological Parameters The physiological parameters consist of volumes and flows; the volumes are required for the tissues or tissue groups represented as boxes whereas flows are associated with the arrows in the model which include alveolar ventilation rate, cardiac output, and organ-specific blood flow rates. Tissue volumes along with their composition, relative to that of blood, determine the extent to which chemicals are diluted within each compartment. The greater the volume of tissue and lipid content, the larger the V_d of lipophilic xenobiotics, thus leading to lower blood concentrations. For example, the volume of adipose tissue represents about 19% to 25% of body weight in adult humans. This adipose volume along with the high P_{tb} for lipophilic organic chemicals (e.g., adipose tissue P_{tb} for DDT = 199) contributes significantly to the V_d (e.g., for DDT 70kg × 0.25 L/kg × 199 = 3483 L) (Haddad et al., 1999; Kirman et al., 2011), and as a source of prolonged internal exposure to such chemicals. In contrast, the tissue blood flow influences the rate at which a chemical in systemic circulation is delivered to a tissue. Tissues with smaller volumes and high perfusion rates will

attain maximal extent of accumulation for a given exposure situation (i.e., steady-state condition) faster compared to other tissues.

The ventilation rate in mammals, in general, is about 15 to 18 L/h/kg but it is not directly proportional to the body weight (BW) of mammals but to the body surface area or approximately to $BW^{0.7}$. Experimental measurements of breathing rates have been obtained with the use of a spirometer, plethysmograph, pneumotachograph, hotwire anemometer, or nonbreathing valves (Krishnan and Andersen, 2007). The cardiac output, a key determinant of the rate at which absorbed chemicals are distributed to and collected from all tissues, has been obtained from dye dilution curves using oximeters. The cardiac output is faster in smaller animals (e.g., mice) than in larger animals (e.g., humans), and again proportional to body surface area or $BW^{0.7}$. The cardiac output in mammals is often comparable to the ventilation rate such that the ratio of perfusion rate:ventilation rate is about 1 in resting individuals, but it can vary as a function of workload and physical activity.

While anthropometric data and breathing rates are often obtained in test animals/subjects, other physiological parameters required for PBPK modeling are obtained from existing literature or calculated on the basis of body weight for each species and life-stage (O'Flaherty, 1994; Brown et al., 1997; Corley et al., 2003; Price et al., 2003a, 2003b; Dewoskin and Thompson, 2008). Table 7-11 presents a summary of frequently used values of basic physiological parameters for adult rats, mice, and humans. Databases on animal and human physiological parameters for various age groups, pathophysiological states, and strains/races are still evolving. While the average value or the range of plausible values of physiological parameters is sufficient for routine model development, the statistical distributions of such parameters would be essential if the model is intended for use in estimating interindividual differences in tissue dosimetry.

Physicochemical Parameters The physicochemical parameters required for PBPK modeling are the partition coefficients, which represent the relative distribution of a nonionized chemical between two matrices at equilibrium. Of these, the tissue to blood partition coefficient (P_{tb}) is a key determinant of the volume of distribution specific to each tissue compartment of a PBPK model, whereas the blood:air partition coefficient (P_b) is a determinant of the pulmonary uptake and clearance of volatile organic chemicals. The pulmonary absorption of chemicals possessing a relatively high P_b is limited by alveolar ventilation rate, whereas that of chemicals with low P_b is limited by cardiac output. Experimentally, the values of P_b have been obtained in vitro by vial equilibration technique conducted at 37°C (Gargas et al., 1989). They can also be computed as the ratio of solubility of a chemical in blood and air as determined by the solubility in neutral lipid, phospholipid, and water components of the blood as follows (Poulin and Krishnan, 1996b):

$$P_b = P_{oa} \cdot (F_{nb} + 0.3F_{pb}) + P_{wa} \cdot (F_{wb} + 0.7F_{pb}), \tag{7-29}$$

where P_{oa} = *n*-octanol:air or vegetable oil:air partition coefficient, P_{wa} = water:air partition coefficient (inverse of the unitless Henry's law constant), F_{nb} = fraction of neutral lipids in blood, F_{pb} = fraction of phospholipids in blood (considered to behave as a mixture of neutral lipids [30%] and water [70%], based on the hydrophobicity characteristics of commercial lecithin [Poulin and Krishnan, 1995]), and F_{wb} = fraction of water in blood.

While this algorithm has worked well for the prediction of P_b of relatively hydrophilic organic chemicals (ketones, alcohols, acetates ester, and diethyl ether), it is insufficient for more lipophilic chemicals such as alkanes, halogenated alkanes, and aromatic hydrocarbons, given their affinity for, and binding to, the hydrophobic pockets in the hemoglobin. The apparent blood:air PC ($P_{b,app}$) for such chemicals has been successfully described with the P_b based on lipid and water solubility as well as binding calculated using the association constant (K_a), the concentration of haemoglobin (C_p), and the concentration of the free form of the chemical in erythrocytes ($C_{a_{free}}$) as shown below (Poulin et al., 1999):

$$P_{ba,app} = P_b \cdot \left(1 + \frac{K_a \cdot C_p}{(1 + K_a \cdot C_{a_{free}})}\right). \tag{7-30}$$

The tissue:blood or tissue:plasma partition coefficients can be estimated experimentally using in vivo pharmacokinetic data or in vitro techniques such as equilibrium dialysis and ultrafiltration (Krishnan and Andersen, 2007). Animal-alternative methods have been emerging, and have given rise to a variety of algorithms accounting for molecular features, physicochemical characteristics, or mechanisms relevant for a training set of chemicals (Table 7-12). In this regard, the simple mechanistic algorithms based on tissue and blood composition take into account the solubility of a xenobiotic in blood and tissues as the sum total of its solubility in neutral lipids, phospholipids, and water, as follows (Poulin and Krishnan, 1995, 1996a, 1996b):

$$P_{tb} = \frac{[P_{ow} \cdot (0.3F_{pt} + F_{nt})] + [0.7F_{pt} + F_{wt}]}{[P_{ow} \cdot (0.3F_{pb} + F_{nb})] + [0.7F_{pb} + F_{wb}]}, \tag{7-31}$$

where P_{tb} = tissue:blood partition coefficient, P_{ow} = *n*-octanol:water or vegetable:oil partition coefficient, F_{nt} = fraction of neutral lipids in the tissue, F_{pt} = fraction of phospholipids in tissue, and F_{wt} = fraction of water in tissue. Table 7-13 summarizes the data on the rat blood and tissue content of neutral lipids, phospholipids, and water.

In order to appreciate the mechanistic basis of P_{tb} using the above equation, let's examine highly lipophilic organic chemicals with $P_{ow} \geq 1000$ not exhibiting plasma protein binding. In this case, the second term in Eq. (7-31) (i.e., water solubility) is negligible compared to the first term (i.e., lipid solubility) in both the

Muscle	0.90	1.00	74

**Data from Poulin et al. (1999).*

numerator and denominator, such that P_{tb} equals the ratio of the content of neutral lipid-equivalents (NLE, i.e., neutral lipids plus 30% of phospholipids) in tissues and blood. For example, in the case of organic chemicals with P_{ow} values ranging from 2738 to 67,200 (cyclohexane, *n*-pentane, methylcyclopentane, 2,2-dimethyl butane, *n*-hexane, 2-methyl pentane, *n*-heptane and 3-methyl hexane), the average human adipose tissue:blood ($P_{at:b}$) is nearly equal to 199, which is the ratio of the NLE content in adipose tissues and blood. Similarly, the reported human adipose tissue:serum partition coefficients of PCBs, PBBs, DDT, dieldrin, mirex, and hexachlorocyclohexane range from 140 to 336, whereas the average ratio of NLE content in human adipose tissue and serum equals 173 (Haddad et al., 2000). In contrast, the P_{tb} of highly hydrophilic chemicals equals the ratio of tissue to blood content of water-equivalents (WE, i.e., water plus 70% phospholipids). For example, in the case of alcohols, acetate esters and ketones with P_{ow} of ≤ 1, the human liver:blood partition coefficients range from 0.81 to 1.00, comparable to the ratio of WE in liver and blood (= 0.86). The ratio of the content of WE in muscle to blood equals 0.90 whereas that for human adipose tissue to blood is about 0.15 (Haddad et al., 2000).

Rate Constants and Biochemical Parameters Rate constants and biochemical parameters required for PBPK modeling include oral absorption rate constant, dermal permeability coefficient, membrane diffusion coefficient, maximal velocity for metabolism, Michaelis parameter, binding association constant, and urinary/biliary excretion rate. These parameters have often been determined on the basis of time-course data collected in vivo or in vitro (Krishnan and Andersen, 2007; Bessems et al., 2014). Typically, data analysis to estimate parameters is conducted using the portion of the time-course curve that is most sensitive to the dominant factor(s). Even though there have been examples of successful integration of in vitro data within PBPK models to simulate in vivo kinetics, the adequacy of in vitro–in vivo extrapolation is not well established for all test systems and processes (Terasaki et al., 1984; Farris et al., 1988; Frederick et al., 1992; Bale et al., 2014; Bessems et al., 2014).

In silico approaches applicable to xenobiotics are evolving based on the rich database for pharmaceutical substances regarding the determinants of oral absorption (i.e., lipophilicity, p*K*a, solubility, particle size, permeability, release kinetics, and dissolution kinetics), as well as mathematical models and algorithms to simulate the rate of drug absorption in humans. For the metabolism constants, there are increasing examples of scaling to in vivo of parameters obtained in vitro with microsomes, post-mitochondrial fractions preparations, and freshly isolated hepatocytes (Bale et al., 2014). Generally, the K_m values obtained in vitro have been used directly or by taking into account the difference in the composition of the in vitro and in vivo matrices, whereas the V_{max} obtained in vitro have been scaled to the whole organism based on the mass recovery of the particular fraction as exemplified by the following equation for the microsomal data:

$$V_{max(\text{in vivo})} = V_{max(\text{in vitro})} \cdot C_{protein} \cdot F_{tissue}, \qquad (7\text{-}32)$$

where $V_{max\ (\text{in vivo})}$ = maximal velocity of metabolism in vivo (mg/min/kg body weight), $V_{max\ (\text{in vitro})}$ = maximal velocity of metabolism in vitro (mg/min/mg microsomal protein), $C_{protein}$ = concentration of microsomal protein (mg/g tissue), and F_{tissue} = fractional volume of the metabolizing tissue (e.g., g liver/kg body weight). In the absence a priori estimates of numerical values of V_{max} and K_m, by specifying the range of plausible values of hepatic extraction in PBPK models (e.g., nearly zero as the lower limit and 100% extraction as the theoretically plausible upper limit), an envelope of the range of blood concentration–time profiles can be generated prior to in vivo experimentation (Fig. 7-14). In silico approaches for predicting metabolic rates and elimination half-lives of xenobiotics in experimental systems and biota are still evolving.

Model Simulation

The equations in a PBPK model are solved to obtain simulation of the toxicokinetics of xenobiotics for a given species, dose, and exposure scenario (Fig. 7-15). In order to solve the MBDE of each tissue compartment, the arterial (input) blood concentration needs to be known, which depends upon mixed venous concentration as well as the chemical input resulting from absorption. The mixed venous concentration in turn depends upon the chemical concentration in venous blood leaving the tissue compartments, such that the input and output of all compartments within the PBPK model are interconnected in a loop-type calculation. Fundamental to the

implementation of these calculations is the integration of the differential equations in the PBPK model. Thus, the temporal evolution of tissue concentration is computed from the amount of chemical in the tissue compartment, resulting from the integration of the differential equation for the rate of change in the amount of chemical in tissue (dA_t/dt) with the use of step-by-step procedures referred to as integration algorithms (e.g., Euler, Gear, Runge-Kutta routines, and predictor-corrector methods) (Rideout, 1991). In the simplest form, the integration algorithm takes into account incremental change in the dependent variable at the end of a simulation period (referred to as the integration interval) and adds it to the initial or starting value, to generate the new value of the dependent variable at the end of each time interval, as follows:

$$A_{t,t1} = A_{t,t0} + \left\{\frac{dA}{dt} \cdot \Delta t\right\}, \tag{7-33}$$

where Δt = integration interval (e.g., $t_1 - t_0$), $A_{t,t1}$ = final amount in the tissue after the integration interval, $A_{t,t0}$ = initial amount in tissue, and dA/dt = the rate of change in the amount of chemical in the tissue compartment during the time interval.

The numerical simulation models, such as the PBPK models, typically require the use of simulation software or packages. There are many commercially available software packages that have features required for rapid construction of PBPK models. Alternatively, spreadsheet programs such as Microsoft EXCEL® can be used to construct simple models and examine the temporal change in the chemical concentration in the various compartments (e.g., Haddad et al., 1996; Krishnan and Andersen, 2007).

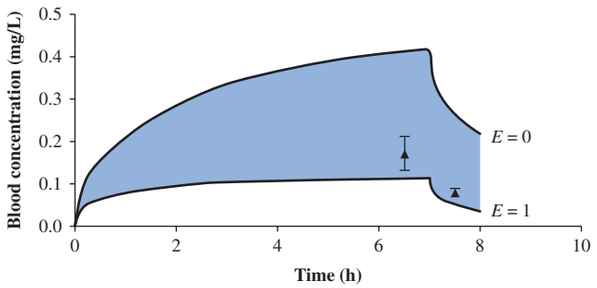

Figure 7-14. Physiologic toxicokinetic model simulations of the envelope of minimum and maximum venous blood concentration profiles of toluene following inhalation exposure, using hepatic extraction ratio (E) of zero (i.e., no metabolism in liver) and one (i.e., complete extraction in liver). The data points correspond to human data obtained from the published literature for the same exposure concentration and scenario.

Model Verification and Evaluation

Model verification focuses on whether the PBPK model is correctly coded (error-free) and the toxicokinetic simulations could be reproduced in a different programming software or computational platform. Model evaluation focuses on comparing the simulations (usually continuous) with experimental toxicokinetic data (usually discrete), and ascertaining whether the model with its structure and parameters is fit to provide output required for a specific end-use. Given that both the PBPK model simulations and experimental data are subject to uncertainty and variability, it is not realistic to expect an exact match between every single data point and the simulation output and therefore PBPK models providing predictions within a factor of 2 of the experimental data have generally been considered to be adequate. As such, the model evaluation focusing on fit-for-purpose and not simply on fit-to-data is becoming the practice. In this regard, WHO (2010) outlined a three-point approach to conduct evaluation of PBPK models with emphasis on the (i) biological basis, (ii) model performance, and (iii) reliability of the model output (i.e., predictions of dose metrics) for the intended end-use (Fig. 7-16). Accordingly, the consideration of biological basis focuses on whether the model structure and range of the input parameters used in model development are biologically plausible, without contradicting the fundamental physiological principles or the mass balance (Table 7-14, column 1). The aspect of model performance focuses on whether the model is able to adequately reproduce toxicokinetic data collected from more than one particular experiment using more than one dose and route of administration (Table 7-14, column 2). Finally, the consideration of reliability of dose metric predictions focuses on how well the PBPK model simulates the dose metrics of relevance to the end-use (e.g., AUCs for interspecies extrapolation in risk assessment), with particular emphasis on the results of uncertainty analysis and sensitivity analyses (Table 7-14, column 3). While the uncertainty analysis involves the evaluation

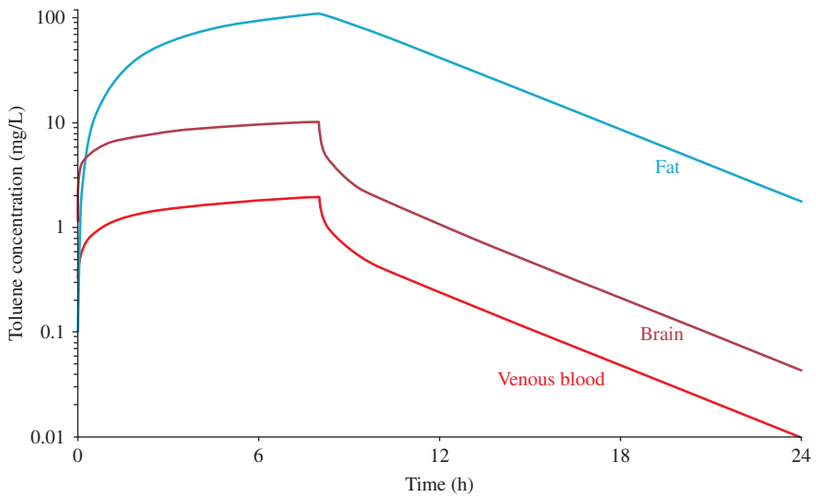

Figure 7-15. *Physiologic toxicokinetic model simulations of the time-course concentrations of toluene in fat, brain, and venous blood in humans exposed to 100 ppm for 8 hours.* (Based on Tardif et al., 1997.)

of the impact of the lack of precise knowledge of parameter values and model structure on toxicokinetic simulations, the sensitivity analysis is a quantitative evaluation of how input parameters influence the model output of dose metrics of relevance (e.g., AUC). As illustrated in Fig. 7-17, if the highly sensitive parameters are also the most uncertain or if the model simulations of dose metric are not sensitive to large variations of the values of some input parameters, then such results can be used to guide the refinement of the model and/or parameters before its intended use. However, if a small change in a parameter value (i.e., the magnitude of which is lower than that associated with measurement variability) only leads to changes in output that are smaller than, or comparable to, the variation in experimental measurement of the dose metric, then the PBPK model would be considered to be reliable. When conducting the uncertainty and sensitivity analyses, it is important to ensure that (i) the numerical values of physiological parameters remain within plausible limits, (ii) the sum of tissue volumes is within or equal to the body weight, (iii) the sum of tissue blood flows is

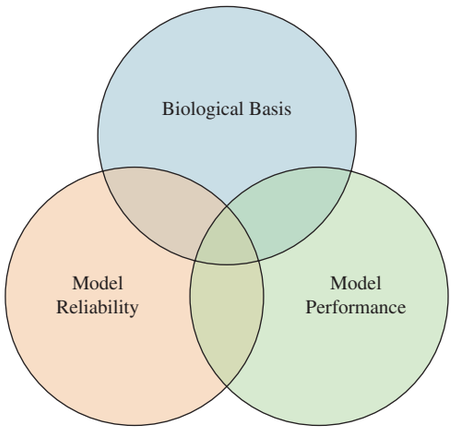

Figure 7-16. *Key aspects for characterizing the level of confidence in physiologic toxicokinetic models intended for specific end-use, as per WHO (2010).*

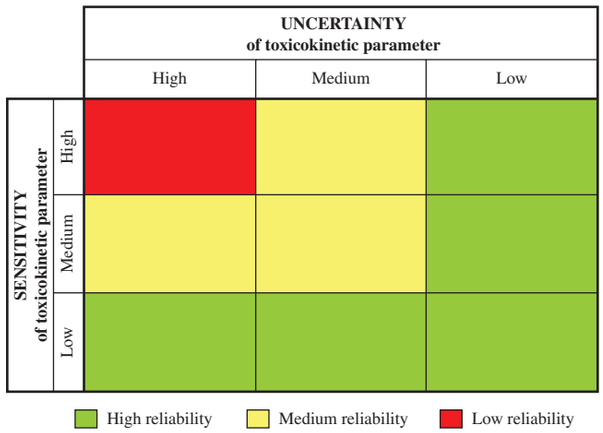

Figure 7-17. *Illustration of the role of sensitivity and uncertainty analyses in determining the reliability of the dose metric predictions, as per WHO (2010).* Sensitivity analysis results are presented as high (value of sensitivity ratio (SR) greater than or equal to 0.5), medium (SR greater than or equal to 0.2 but less than 0.5), or low (SR greater than or equal to 0.1 but less than 0.2). Uncertainty analysis results are summarized as high uncertainty (value could be a factor of 2 or higher), medium uncertainty (value could be a factor between 0.3 and 2), or low uncertainty (value could be a factor of 0.3 or lower). Uncertainty is defined as the ratio of the 95th percentile over the median value for the dose metric. A sensitivity ratio (SR) of 1 implies that a 1% change in input of a parameter value leads to a 1% change in dose metric prediction.

Table 7-14

Checklist for Characterizing the Level of Confidence in Physiologically Based Toxicokinetic (PBPK) Models

BIOLOGICAL BASIS OF PBPK MODELS	PERFORMANCE OF PBPK MODELS	RELIABILITY OF PBPK MODELS
• The sum total of the tissue blood flow rates equals the cardiac output specified within the model. • The sum total of the volumes of compartments equals the soft tissue volumes or body weight, as the case may be. • The values of tissue volumes and tissue blood flow rates (individual or group) specified in the model are within the documented range for the particular species and life stage. • The ventilation:perfusion ratio specified in the model is within physiological limits. • The allometric scaling of parameters, if applicable, is consistent with the known physiological principles. • The major sites/processes of absorption, distribution and clearance are included in the model. • The mathematical equations of ADME do not violate the known theoretical or biological principles. • The input parameters adequately reflect the characteristics of the subject, population, chemical, and exposure pathway.	• The PBPK model consistently reproduces the general trend of the toxicokinetic data (i.e., peaks, bumps, and valleys, saturation of metabolism). • The PBPK model predictions are within an acceptable level of correspondence with the experimental data (e.g., within a factor of two). • The PBPK model reproduces the chemical-specific toxicokinetic data under various experimental conditions or exposure scenarios.	• The PBPK model is capable of providing reliable predictions of the concentration–time course of the candidate dose metrics in the target organ or a suitable surrogate compartment (e.g., blood). • The data used for calibrating and/or evaluating the PBPK model are reliable. • The sensitivity of the output (dose metric) to change in numerical values of input parameters has been characterized for relevant human or animal exposures. • The uncertainty in PBPK model predictions of dose metric has been assessed for the relevant exposure conditions.

equal to the cardiac output, (iv) the mass balance is respected at all times (amount of chemical absorbed = amount in body + amount metabolized + amount of excreted), and (v) the covariant nature of parameters is taken into account, in conformity with the statistical and biological basis (e.g., the subject with the lowest breathing rate is not combined with the highest cardiac output).

In conclusion, the PBPK model is mechanistically based and more complex than the classical data-based toxicokinetic models but it is still a simplified representation of the biological system under study. The PBPK models, as other mechanistic models, only account for those determinants and processes that are hypothesized to be critical by the investigator(s). The complexity and number of compartments are thus not reflective of the accuracy and usefulness of a given PBPK model, but are considered to be critical for simulating the toxicokinetics of the chemical in a given experimental subject or species. Finally, the species, developmental stage, exposure route, and dose range corresponding to the toxicity study and the PBPK modeling study should be compared to select the appropriate model for use in interpreting a toxicity study.

TOXICOKINETIC TOPICS AND APPLICATIONS

The interpretation of toxicology studies has sometimes been conducted on the basis of administered dose or absorbed dose when such data were available. However, the dose to the target site is the more desired and relevant dose metric. In this regard, the toxicokinetic models are useful for estimating systemic exposure, in terms of the toxic form of a chemical (parent or metabolite) over a specific duration in blood or the target organ. Such a measure reflective of the dose to the target is critical not only for interpreting the toxicity data but also for conducting various extrapolations in the case of systemically acting chemicals (i.e., those chemicals that induce toxicity at target sites distant from the portals of entry by accessing them via systemic circulation). The following sections describe these topics and applications facilitated by toxicokinetic parameters and models.

Nonlinear Kinetics

The distribution and clearance of most chemicals follow first-order kinetics in the low-dose region. Accordingly, the K_{el}, V_d, CL, and $t_{1/2}$ are expected to be same in the low-dose range (i.e., no dose-dependent change in kinetic parameters occurs under first-order condition). In other terms, under first-order conditions, the dose metrics (e.g., C_{max}, AUC) will be nearly identical when compared on the basis of unit dose (e.g., per µg/kg/day) or exposure concentration (per ppm). A semilogarithmic plot of blood concentration versus time over a range of doses will show a set of parallel lines such that blood concentration at a given time or the AUC_0^∞ remain proportional to dose. Thus, a twofold change in dose (µg/kg/day) will result in a twofold change in blood concentration at a given time after dosing or in the value of AUC_0^∞ if first-order conditions prevail in the dose range. However, for some toxicants, as the dose increases, its V_d and/or CL may change, showing nonlinear or dose-dependent kinetics (Fig. 7-18). Enzyme-mediated metabolism, active transport processes, and protein binding have finite capacities and therefore can be saturated. For instance, most metabolic enzymes operate in accordance to Michaelis–Menten kinetics (Table 7-10), such that the rate of metabolism (amount per unit time) depends upon the unbound concentration of the substrate ([S]) as well as intrinsic clearance ($CL_{int} = \frac{V_{max}}{K_m + [S]}$), the latter representing the ability of the enzyme machinery to cleanse the medium in which the substrate is present (e.g., blood) (Gibaldi and Perrier, 1982; Rowland and Tozer, 2011). Accordingly, at very high substrate concentrations (i.e., [S] >> K_m), the rate of metabolism will be equal to V_{max} (i.e., the maximal capacity of the enzyme) and thus reflective of a zero-order process, that is, the rate of metabolism remains the same regardless of the substrate concentration when the latter is well above the K_m. In contrast, at very low substrate concentrations (i.e., when [S] is very small and negligible compared to K_m), the rate of metabolism is proportional to the concentration of the substrate (i.e., first-order process) because CL_{int} remains constant and equal to V_{max}/K_m. Taken together, it implies that as the dose increases and the unbound concentration of a toxicant at the site of metabolism approaches or exceeds the K_m (substrate concentration at one-half of V_{max}), the increase in metabolism rate becomes less than proportional to the dose and eventually approaches a maximum at very high doses. The model simulations shown in Fig. 7-19 indicate the nonlinear nature of blood AUC and C_{max} in the selected dose range for toluene. In such cases, the high dose to low dose extrapolation of tissue dosimetry should not be conducted assuming linearity; rather it should be performed using tools such as the PBPK models that account for the nonlinear mechanism and its determinants.

The transition from first-order to zero-order (or saturation) kinetics is important in toxicology because it can lead to prolonged persistence of a compound in the body after a single dose or an acute exposure, and excessive accumulation during repeated or chronic exposure. Some of the salient characteristics of nonlinear kinetics include the following: (i) the decline in the concentrations of the parent chemical in the body is not exponential, (ii) AUC_0^∞ and amount metabolized are not proportional to the dose, (iii) V_d, CL, K_{el} (or β), or $t_{1/2}$ change with increasing dose, (iv) the composition

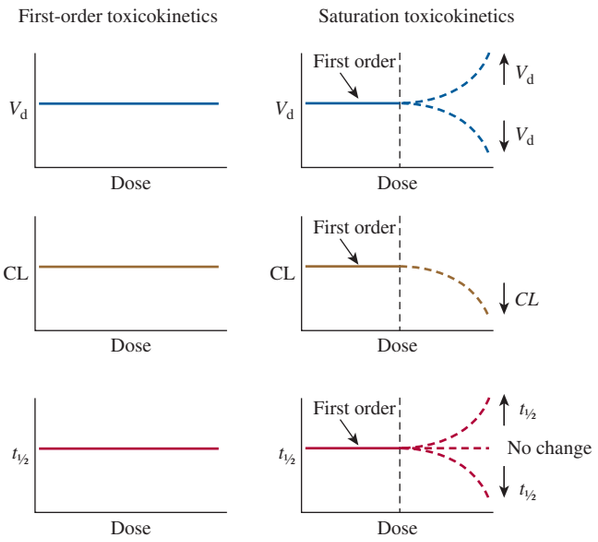

Figure 7-18. *Changes in V_d, CL, and $t_{1/2}$ following first-order toxicokinetics (left panels) and following saturable toxicokinetics (right panels).* Vertical dashed lines in the right panels represent point of departure from first-order to saturation toxicokinetics. Toxicokinetic parameters that follow first-order toxicokinetics are independent of dose. When plasma protein binding or elimination mechanisms are saturated with increasing dose, such parameter estimates become dose-dependent. V_d may increase, for example, when protein binding is saturated, allowing more free toxicant to distribute into extravascular sites. Conversely, V_d may decrease with increasing dose if tissue protein binding saturates. Then, toxicant may redistribute more freely back into plasma. When toxicant concentrations exceed the capacity for biotransformation by metabolic enzymes, overall clearance of the toxicant decreases. These changes may or may not have effects on $t_{1/2}$ depending upon the magnitude and direction of changes in both V_d and CL.

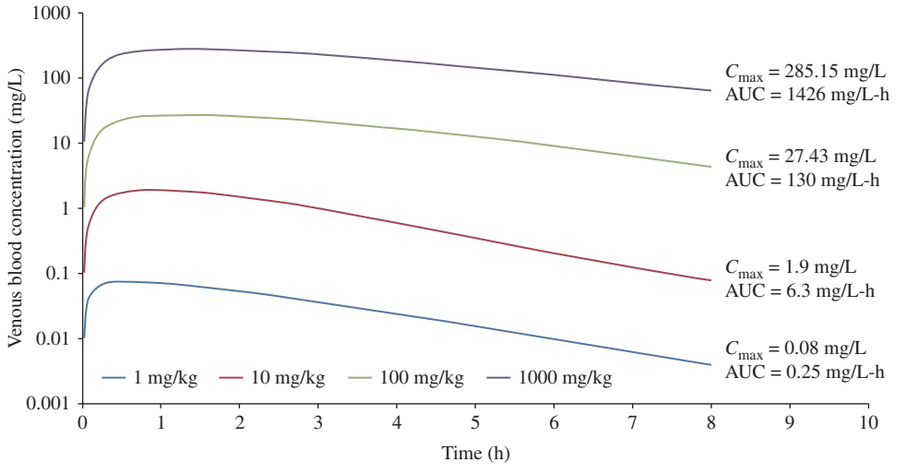

Figure 7-19. *Physiologic toxicokinetic model simulations of the venous blood concentration of toluene in humans administered a single oral dose of 1, 10, 100, and 1000 mg/kg.*

of excretory products changes quantitatively or qualitatively with the dose, and (v) dose–response curves depict a steeper change in response to an increasing dose, starting at the dose at which saturation effects become evident. In addition to the complication of dose-dependent kinetics, there are toxicants whose clearance might change over time (i.e., time-dependent kinetics). A common cause of time-dependent kinetics is autoinduction of metabolizing enzymes through activation of gene transcription by certain drugs and xenobiotics. The classic example of autoinduction is with the antiepileptic drug, carbamazepine. Daily administration of carbamazepine leads to a continual increase in clearance and shortening in $t_{1/2}$ over the first few weeks of therapy (Bertilsson et al., 1986).

PBPK models facilitate high-dose to low-dose extrapolation of tissue dosimetry by accounting for the mechanism(s) underlying the nonlinear kinetic behavior of chemicals (e.g., saturable metabolism, enzyme induction, enzyme inactivation, protein binding, and depletion of glutathione reserves) (Clewell and Andersen, 1987, 1994). Quantitative descriptions of such mechanisms are essential for any toxicokinetic model to facilitate extrapolation or interpolation of dose metrics from high dose to low dose. The capacity-limited hepatic metabolism leading to the nonlinear dose–response behavior is best illustrated with vinyl chloride (Slikker et al., 2004). Similarly, in the case of dichloromethane, the PBPK model facilitated high-dose to low-dose extrapolation of the potential dose metrics by accounting for the saturation of CYP2E1-mediated metabolism and disproportionate increase in glutathione *S*-transferase-mediated metabolism with increasing doses (Andersen et al., 1987, 1991). For the conduct of high-dose to low-dose extrapolation with PBPK models, frequently no change in the numerical values of input parameters would be required, with the exception of the administered dose or exposure concentration.

Single versus Repeated Dose Kinetics

Continuous or chronic exposure to a chemical can lead to its accumulation in the body depending upon its elimination half-life and interval between the doses. For example, lipophilic chemicals with large V_d and very small CL exhibit long half-lives and accumulate as the exposure continues. On the contrary, for a chemical with a very small $t_{1/2}$ compared to the time interval between doses, it is likely to be eliminated almost completely before the next dose such that there would be no significant accumulation. Let's consider a chemical with $t_{1/2}$ of 4 hours is administered to experimental animals once every 24 hours. In this case, the amount eliminated would be proportional to the body burden (i.e., first-order elimination kinetics) in the dose range of interest. Thus, the amount eliminated after one half-life or 4 hours = 50%, two half-lives = 75%, three half-lives = 87.5%, four half-lives = 93.75%, five half-lives = 96.875%, six half-lives = 98.438%, seven half-lives = 99.219%, and eight half-lives = 99.61%. If the second dose is administered at 4 hours, that is, after one half-life, then 50% of the chemical from the first dose will still be in the body to which the second dose adds leading to higher blood concentration than what was seen after a single dose. The narrower the interval between doses or the shorter the dosing interval compared to the $t_{1/2}$, the faster the attainment of steady state will be. Fig. 7-20 shows the same time to attain 50% steady state for various rates of intake; on the contrary, the steady-state blood concentration is strictly proportional to the intake rate. Typically, the rise in blood concentration is relatively rapid after dosing, as it is governed by the early (distribution) half-life, and becomes slower at later times when the terminal (elimination) half-life becomes dominant. Therefore, when the doses are given at certain intervals of time (and not in a continuous fashion), the fraction eliminated between two dosing intervals needs to be accounted for computing the dose metrics.

Let's consider that a single dose of 100 mg of a chemical (with an elimination rate constant K_{el} of 0.693 day^{-1}; elimination half-life of 1 day; and V_d = 10 L) is given to rats once per day. The initial blood concentration in this case would be 10 mg/L, which then becomes 5 mg/L after 1 day (i.e., 24 hours), and after the second dose it raises to 15 mg/L, which then becomes half-that-quantity after another day (i.e., 7.5 mg/L), and so on. The fraction eliminated during a given interval of time (τ) and the maximal and minimal concentrations attained during repeated doses given at intervals of τ can be calculated by accounting for the fraction eliminated during that time frame (i.e., $1 - e^{-K_{el} \cdot \tau}$). In the example presented in Fig. 7-21, for chemical A with K_{el} = 0.0007 h^{-1}, the concentrations increase markedly after each additional dose. If the K_{el} is increased to 0.01 h^{-1}, then 21% is eliminated between doses as shown in Fig. 7-21 for chemical B. On the contrary, if the elimination is rapid, then it is likely that the "between-dose" accumulation could be negligible (Fig. 7-21, chemical C). Therefore, the knowledge of the fraction eliminated during the time interval between doses, and the extent to which C_{max} and C_{min} fluctuate during a dosing interval, figure among key considerations in designing toxicity studies.

At a fixed level of continuous exposure, the toxicant in the body reaches a steady state when the intake rate equals its elimination rate such that the body burden stays constant, as illustrated by the conceptual PBPK model depicted in Fig. 7-22. Steady-state concentration of a toxicant in blood (C_{ss}) is related to the intake rate (mg/kg/day) and clearance (L/kg/day) as follows:

$$C_{ss} = \frac{\text{Intake Rate}}{\text{CL}}. \qquad (7\text{-}34)$$

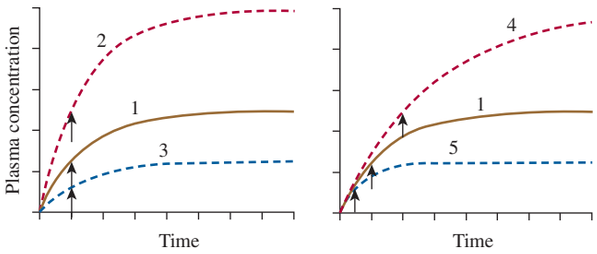

Figure 7-20. *Accumulation of plasma toxicant concentration over time during constant, continuous exposure as a function of exposure level (left panel) and elimination half-life (right panel).* These simulations are based on a one-compartment model at a constant apparent volume of distribution. Case 1 serves as the reference with an elimination half-life set equal to one arbitrary time unit. In the left panel, which illustrates accumulation of toxicant as a function of exposure level, exposure level is raised by twofold in case 2 and lowered by 50% in case 3. The changes in eventual steady-state concentration are proportional to the changes in exposure level, that is, increased by twofold in case 2 and decreased by 50% in case 3. During continuous exposure, 50% of steady state is achieved in one half-life. Near plateau or steady state (>90%) is reached after four half-lives. Since the elimination half-life is constant across cases 1 to 3 in the left panel, the time it takes to attain 50% of steady-state concentration (see arrows) is the same. Right panel illustrates the influence of elimination half-life and clearance on accumulation at a fixed constant rate of exposure. Case 4 represents a 50% decrease in clearance and a corresponding twofold increase in elimination half-life compared to case 1. Case 5 represents a twofold increase in clearance and a corresponding 50% decrease in elimination half-life. Changes in both the time to attain steady state and the steady-state concentration are evident. In case 4, the steady-state concentration increased by twofold as a result of a 50% reduction in clearance, and the time to achieve 50% of steady state increased by twofold as a result of the prolonged elimination half-life. In case 5, the steady-state concentration is reduced by 50%, while the time to reach 50% steady state is shortened by 50%.

The daily dose in the above equation should account for the route-specific bioavailability (F) and the CL in turn can be calculated as $V_d.K_{el}$. When the target steady-state blood or plasma concentration is fixed (e.g., in case of therapeutic application), the product of CL and C_{ss} equals the maintenance dose rate. The C_{ss} as derived in Table 7-15 is reflective of the AUC averaged over the time interval τ, whereas the product of the average C_{ss} and V_d equals the average body burden at steady state.

The compartmental models including the PBPK models described in the preceding sections are useful in the estimation of blood and tissue concentrations associated with a single dose or repeated doses given by various routes, and this can frequently be accomplished using a single set of parameters. In other instances, re-estimation or adjustment of parameter values might be necessary to accommodate the observed or anticipated change in input parameters with time (e.g., change in V_d due to body fat content, change in CL_{int} due to enzyme induction). Fundamentally, the rate of change in the amount of chemical in non-metabolizing tissues in PBPK models becomes equal to zero at steady state, such that the tissue concentrations remain stable during repeated exposures. The steady-state blood concentration obtained with the PBPK model will be the same as that obtained using Eq. (7-34) (Andersen, 1981; Gibaldi and Perrier, 1982). PBPK models also have been used to predict the kinetic behavior and tissue dosimetry of chemicals during unusual exposure scenarios (e.g., adjusted threshold limit values during extended hours of work, physical activity/work load, pregnancy and lactation, or coexposure to chemicals) (Clewell and Andersen, 1987; Krishnan et al., 2002; Corley et al., 2003).

Metabolite Kinetics

Metabolism of a parent chemical or drug can result in bioactivation or detoxication, with the resulting products subjected to further metabolism to more active or inactive moieties. When the toxicity is attributed to the biotransformation product(s), the formation and subsequent disposition kinetics of a toxic metabolite are of interest not only from the perspective of toxicology but also biological monitoring. As the parent chemical is transformed into a metabolite, the blood concentration of the metabolite rises depending upon its reactivity, V_d, and CL. Once formed, the metabolite might exhibit reactivity/stability, be subjected to further biotransformation reactions to form other metabolites, or undergo excretion via the kidneys

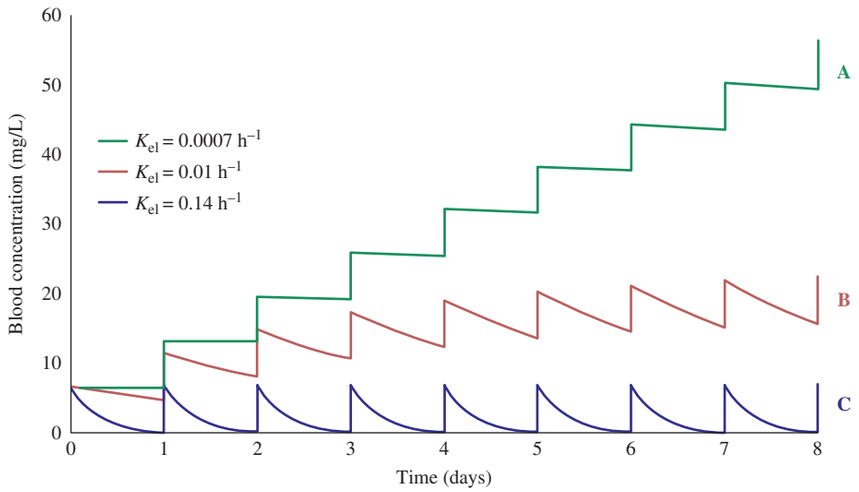

Figure 7-21. *Time-course plots of the blood concentrations of xenobiotics A, B, and C administered once a day.* The first-order elimination rate constants are 0.0007 h^{-1}, 0.01 h^{-1}, and 0.14 h^{-1}, respectively for A, B, and C.

Table 7-15

Set of Equations to Understand Steady-State Kinetics

DESCRIPTION	EQUATION
Rate of change in the amount of a chemical in the body	$\frac{dA}{dt} = \text{Dose rate} - (A_t \cdot K_{el})$
Rate of change at steady state	$\text{Dose rate} - (A_t \cdot K_{el}) = 0$
Amount in body at steady state	$A_{ss} = \frac{\text{Dose rate}}{K_{el}}$
Blood concentration at steady state	$C_{ss} = \frac{\text{Dose rate}}{V_d \cdot K_{el}}$
Blood concentration at steady state in relation to clearance	$C_{ss} = \frac{\text{Dose rate}}{\text{CL}}$

Abbreviations: A_{ss}, amount in the body at steady state; CL, clearance; C_{ss}, blood concentration of chemical at steady state; Dose rate, absorbed dose per unit time; K_{el}, first-order elimination constant; V_d, Volume of distribution.

or bile; hence at some point in time, the blood concentration of the metabolite exhibits a peak and falls thereafter. Fig. 7-23 illustrates the blood concentration–time course of a primary metabolite in relation to its parent compound under contrasting scenarios. The left panel shows the case when the elimination rate constant of the metabolite is much greater than the overall elimination rate constant of the parent compound. Here, the terminal decline of the metabolite parallels that of the parent compound; the metabolite is cleared as quickly as it is formed or its washout is rate-limited by conversion from the parent compound. The right panel shows the opposite case when the elimination rate constant of the metabolite is much lower than the overall elimination rate constant of the parent compound. The slower terminal decline of the metabolite compared to the parent compound simply reflects a longer elimination half-life of the metabolite. It should also be noted that AUC_0^∞ of the metabolite relative to the parent compound is dependent on the partial clearance of the parent chemical to the metabolite and clearance of the derived metabolite. A biologically active metabolite assumes toxicological significance when it is cleared much less efficiently than the parent compound and/or exhibits accessibility and reactivity in the target site.

Cross-Route Dose Extrapolation

The comparison or extrapolation of toxicity data across exposure routes can be conducted for systemically acting chemicals based on administered dose or more appropriately based on toxicokinetic considerations. Cross-route comparisons or extrapolations conducted on the assumption of 100% bioavailability of administered dose (mg/kg/day) fail to take into account the significance and impact of route-specific first-pass effect, as well as the differences in rates and extent of absorption between exposure routes that may impact the dose metric of relevance to the mode of action (Pauluhn, 2003). The data on route-specific bioavailable fraction are therefore useful for the conduct of route-to-route extrapolation of toxicokinetically equivalent dose of chemicals. For example, the bioavailable dose for each exposure route can be calculated by multiplying the administered dose with the route-specific bioavailability (F_{route}). The extrapolation of equivalent dose between two exposure routes (e.g., oral to dermal route in units of mg/kg/day) is then conducted on the basis of the ratio of the route-specific bioavailable fraction (F_{route1}/F_{route2}) as follows (IGHRC, 2005):

$$\text{Dose}_{route2} = \text{Dose}_{route1} \frac{F_{route1}}{F_{route2}}. \quad (7\text{-}35)$$

A more scientifically sound approach would involve the use of PBPK models, by accounting for the species- and route-specific rate and magnitude of absorption as well as first-pass effect to facilitate the conduct of route to route extrapolation on the basis of equivalent tissue dose of toxic moiety (Fig. 7-24; Clewell and Andersen, 1987, 1994; Gerrity et al., 1990). For example, a 4-hour inhalation exposure to 83.4 ppm chloroform in the rat is equal to an oral dose of 1 mg/kg, as determined with PBPK models on the basis of equivalent AUC_{blood} (U.S. EPA, 2006). When the dose metric based on parent compound is the basis of cross-route equivalence, it can be computed as being equal to the bioavailable dose divided by the total clearance (Valcke and Krishnan, 2013, and references cited therein), for chronic exposure situations leading to steady state. Accordingly,

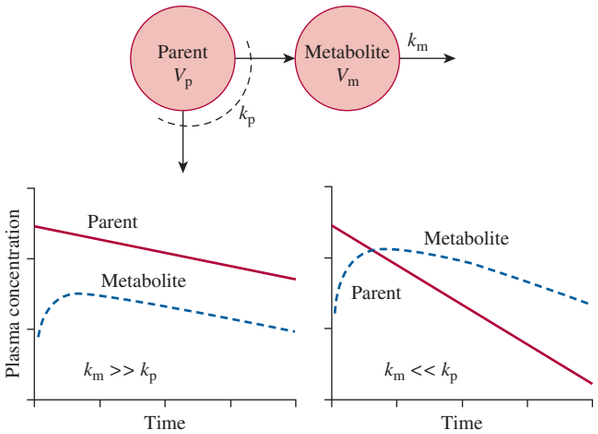

Figure 7-23. *Plasma concentration–time course of a primary metabolite and its parent compound under contrasting scenarios: when elimination of the metabolite is much more rapid than its formation ($k_m >> k_p$ lower left panel) and when elimination of the metabolite is much slower than its formation ($k_m << k_p$, lower right panel).* Semilogarithmic plots are shown to compare the slope of the terminal decline of parent compound and its metabolite. The top panel shows the model for conversion of the parent compound to a single metabolite. Note that the elimination rate constant for the parent compound (k_p) includes both the rate constants for metabolism and extra-metabolic routes of elimination. k_m is the elimination rate constant for the derived metabolite. When $k_m >> k_p$, the terminal decline of the metabolite parallels that of the parent compound, that is, metabolite washout is rate-limited by its formation. When $k_m << k_p$, the terminal decline of metabolite concentration is much slower than that of parent compound, that is, metabolite washout is rate-limited by its elimination.

given that the total clearance (sum of renal, hepatic, and pulmonary clearances, expressed as L/day) is the same regardless of the exposure route, the extrapolation of oral dose (mg/kg/day) to inhalation concentration (mg/m^3) can be conducted as follows:

$$\text{Dose}_{\text{inh}} = \frac{\text{Dose}_{\text{oral}} \times \text{BW} \times F_{\text{oral}}}{Q_{\text{alv}}}, \tag{7-36}$$

where BW = body weight, F_{oral} = bioavailable fraction for the oral route (accounting for first pass effect and absorption by the oral route) associated with the relevant dose (e.g., NOAEL), and Q_{alv} = alveolar ventilation rate (m^3/day).

Interspecies Dose Extrapolation

The extrapolation of toxicologically equivalent dose from one species to another (typically from test animal species to humans) has been historically addressed with the use of a factor of 10 (Dourson et al., 1996). WHO (2005), based on work by Renwick (1993, 1999), subdivided it into toxicokinetic and toxicodynamic components underlying interspecies differences and interindividual variability (Fig. 7-25). The default value of the toxicokinetic component is equal to interspecies ratio of BW to a fractional power (0.67 to 0.75), consistent with the observations that several physiological parameters (GFR, breathing rate, cardiac output) and volume of extracellular water are more closely related to body surface rather than body weight of mammals. It is considered that such allometric dose adjustments (e.g., $\text{Dose}_{\text{human}}(\text{mg/kg/d}) = \text{Dose}_{\text{animal}}(\text{mg/kg/d})\left(\frac{\text{BW}_{\text{Animal}}}{\text{BW}_{\text{Human}}}\right)^{0.33}$) not only reflect interspecies differences in body surface area and physiological flow rates but also provide toxicokinetically equivalent

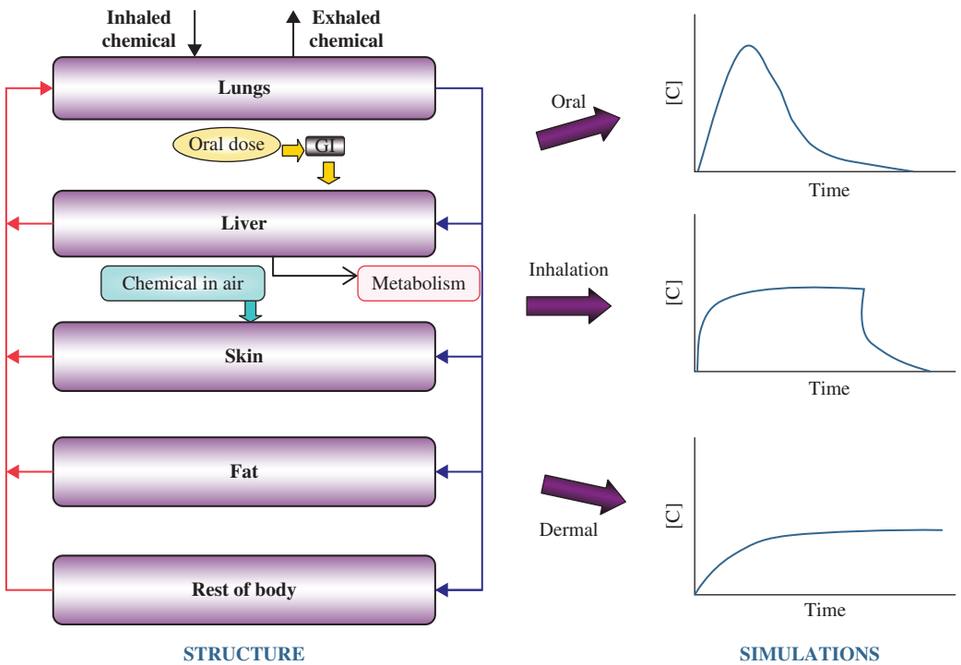

Figure 7-24. *Illustration of the use of physiologic toxicokinetic model to simulate the blood concentration [C] as a function of time for three routes of exposure: oral, inhalation, and dermal.* For simulating the route-specific toxicokinetics of the chemical, only the route-specific input parameters are specified along with the chemical concentration in the corresponding exposure medium.

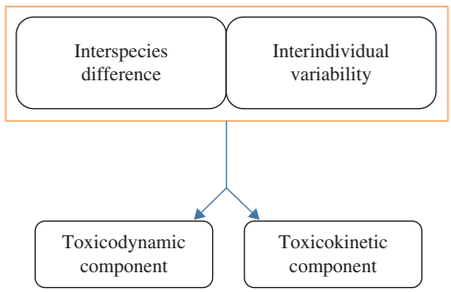

Figure 7-25. *Components of interspecies difference and interindividual variability in response associated with exposure to toxicants.* As per WHO (2005), the toxicokinetic and toxicodynamic components of rat to human differences are given values of 4 and 2.5, respectively, for a total combined (multiplicative) factor of 10. In consideration of interindividual variability in responses from a risk assessment perspective, WHO (2005) suggested default values of 3.16 each for the toxicokinetic and toxicodynamic components, which in turn can be refined with chemical-specific data.

doses across species as long as the parent chemical is the potential toxic moiety and AUC_{blood} is the appropriate measure of dose to target tissue. Such a generic approach for extrapolating doses across species, particularly for the chronic oral exposure leading to steady-state condition, will hold when CL of a xenobiotic is proportional to the body surface area in both animals and humans. Otherwise, it is more relevant to conduct interspecies extrapolation on the basis of chemical-specific data on the dose metrics of relevance to the mode of action (AUC, C_{max}) or the associated toxicokinetic parameter (CL). Thus, the chemical-specific animal to human kinetic adjustment factor (AK_{AF}) is calculated as the ratio of clearance ($AK_{AF} = \frac{CL_{Animal}}{CL_{Human}}$) or the ratio of dose metrics ($AK_{AF} = \frac{AUC_{Human}}{AUC_{Animal}}$) (WHO, 2005). In this regard, the PBPK models are useful for computing AK_{AF} based on the simulation of alternative dose metrics for the dose levels and exposure scenarios of relevance to a toxicological evaluation or risk assessment (Fig. 7-26).

The application of PBPK models for interspecies extrapolation of the toxicokinetics and internal dose of xenobiotics is performed in several steps. The initial step involves the development of a PBPK model in the test animal species and comparison of toxicokinetic simulations with experimental data. Following evaluation of the biological basis, model performance and reliability of dose metric simulations, the physiological parameters of the PBPK model are scaled to humans and the chemical-specific parameters for the species of interest (e.g., humans) are replaced. Whereas the adult physiological parameters vary coherently across species, the rates and affinities for various metabolic reactions across species are not generalizable. For several xenobiotics showing high hepatic extraction ratios in both animals and humans, the scaling of V_{max} to the 3/4th power of body weight, while keeping the K_m species-invariant, has proved to be a useful first approximation. The confidence will be greater if the metabolic parameters are obtained in vitro using human tissues/components for incorporation within PBPK models or following a parallelogram approach to make use of in vivo parameter estimates in rodents as well as in vitro estimates in both rodents and humans (Reitz et al., 1988; Lipscomb et al., 1998). Qualitative differences, if any, between species (e.g., rat to fish) can also be factored into the PBPK models in addition to quantitative differences in mechanistic determinants of toxicokinetics for the conduct of interspecies extrapolation.

Interindividual Kinetic Variability

The toxicokinetic parameters (e.g., CL, $t_{1/2}$) and dose metrics (e.g., C_{max}, AUC) for a xenobiotic may vary among individuals and between various subgroups in the human population. The interindividual variability in toxicokinetics, as characterized by the human kinetic adjustment factor (HK_{AF}), is represented by the ratio between the upper percentile value (i.e., 95th, 99th) and its central tendency value in the entire population of a toxicokinetic parameter or dose metric of relevance for a given chemical (Meek et al., 2003; WHO, 2005; Valcke and Krishnan, 2014). Alternatively, the HK_{AF} is computed as the ratio between an upper percentile value in a selected sensitive subpopulation and the central tendency value for the general population (i.e., $\frac{CL_{Median}}{CL_{Subpopulation}} = \frac{AUC_{Subpopulation}}{AUC_{Median}}$) (Fig. 7-27). In addition to the knowledge of population distribution of chemical-specific toxicokinetic parameters or dose metrics, an understanding of the mode of action and putative toxic moiety of a chemical is fundamental to the derivation of HK_{AF}. The population distribution of dose metrics can also be obtained with PBPK models by accounting for the population distribution of physiological parameters, metabolizing enzymes (including polymorphism), and rates of toxicokinetic processes. By using inputs sampled from statistical distributions for each PBPK model parameter, the Monte Carlo approach facilitates the simulation of distributions of the output, that is, dose metric in a population. Using the PBPK predictions of dose metric corresponding to the 95th percentile and 50th percentile for unimodel, normal distribution, the magnitude of HK_{AF} has been computed (Naumann et al., 2001). Alternatively, subject-specific PBPK models can be constructed to evaluate the variability of dose metrics as a function of gender, age, and lifestage (birth, pregnancy, lactation) or physiological state (obesity) by accounting for quantitative changes in physiological parameters, tissue composition, and metabolic activity (O'Flaherty 1994; Corley et al., 2003; Price et al., 2003a, 2003b; Nong et al., 2006; Valcke and Krishnan, 2013).

Kinetic Interactions During Mixed Exposures

Toxicokinetic interactions during mixed exposures result when one chemical alters the mechanistic determinant of another chemical at the level of absorption (e.g., alteration of ventilation rate, skin permeability coefficient), distribution (e.g., competition for binding to hemoglobin, albumin, metallothionein, alteration of the concentrations of binding proteins, alteration of tissue blood flow), metabolism (e.g., enzyme induction or inhibition), or excretion (e.g., GFR) (Krishnan and Brodeur, 1994). Such interactions result in an increase or decrease in the internal dose per unit administered dose during mixed exposures in comparison with the individual chemical exposures. For example, during mixed exposures, xenobiotics may compete directly with each other for an enzymatic binding site (competitive inhibition), bind directly to the enzyme-xenobiotic complex but not to the free enzyme (uncompetitive inhibition), or do both of these (noncompetitive inhibition) (Segal, 1975). In such cases, toxicokinetic analysis should account for the nonlinearity arising from not only the saturable metabolism of individual mixture components but also the impact of the metabolic inhibition as a function of the concentration and affinity of one mixture component (substrate) in comparison with the free concentration and potency of another mixture component (inhibitor). When induction of metabolizing enzymes occurs, the toxicokinetic analysis would indicate that the impact is more pronounced in cases where hepatic

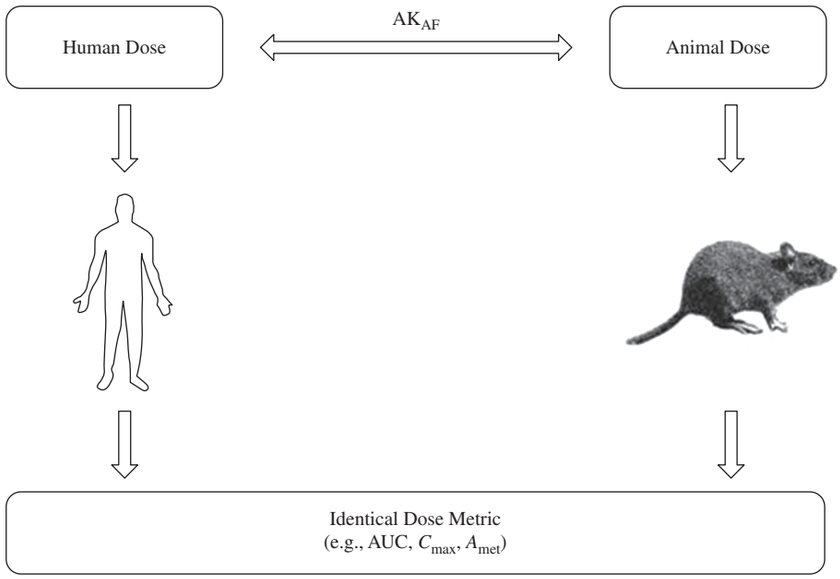

Figure 7-26. *Interspecies extrapolation in toxicokinetics.* The animal to human kinetic adjustment factor (AK_{AF}) reflects the difference in the external (or administered) dose producing the same level of the dose metric in the test animals and humans. (Adapted from U.S. EPA, 2014.)

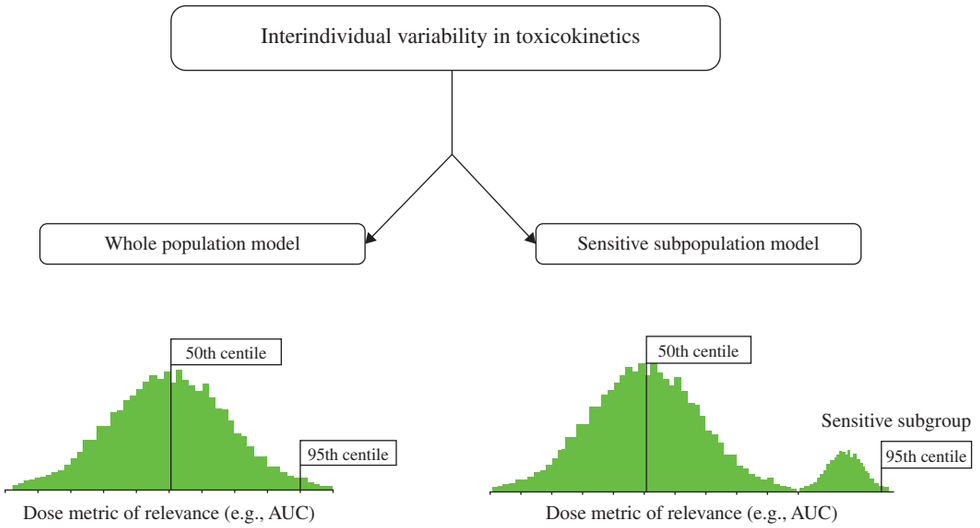

Figure 7-27. *Illustration of the use of toxicokinetic data (e.g., area under the concentration vs. time curve [AUC]) to characterize the magnitude of interindividual variability, in consideration of the simulated or measured values in the whole population (left panel) or a sensitive subgroup within a population (right panel).*

metabolism is capacity-limited (e.g., high doses, xenobiotics exhibiting low hepatic extraction ratio).

Most experimental studies and modeling tools have historically dealt with binary mixtures, due to their inability to account for and interpret the higher order interactions among components. The PBPK model framework allows the tracking of changes in mechanistic determinants induced by each of the mixture components to simulate the impact on the toxicokinetics in more complex mixtures. Tardif et al. (1997) conducted PBPK modeling of mixtures by interconnecting individual chemical models mechanistically at the site of interaction (e.g., two mixture components A and B competing for metabolizing enzymes in liver) (Fig. 7-28). In this approach, when a third chemical C is added to the binary mixture model, the PBPK model not only simulates the new binary interactions involving C (i.e., C-A, C-B), but also the modulatory effect of C on the existing binary interaction between A and B because all components of the mixture are linked. Based on this analogy, PBPK models facilitate prediction of the impact of the addition of another chemical D to the ternary mixture, and so forth because every new chemical becomes an integral part of the existing network of binary interactions (Tardif et al., 1997; Krishnan et al., 2002). Conceptually then, with increasing complexity of mixtures, the inhibition constant for binary interactions is not modified during mixed exposures; rather the free concentration of the inhibitors is

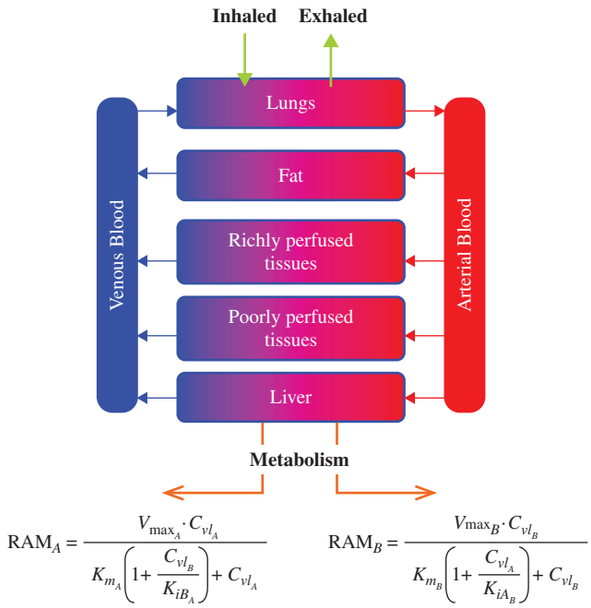

Figure 7-28. *Physiologic toxicokinetic model of inhalation exposure of workers to two volatile organic chemicals.* The two chemicals (A and B) circulate simultaneously and interact with each other in the liver compartment. Chemical A and chemical B compete and inhibit each other's metabolism by the hepatic CYP2E1. RAM is the rate of the amount metabolized, V_{max} is the maximal velocity of metabolism, K_i is inhibition constant, K_m is the Michelis affinity parameter, and C_{vl} is the free concentration of the chemical at the site of metabolism.

altered according to the potency and number of the other inhibitors as well as their concentrations in systemic circulation.

Interpretation of Human Biomonitoring Data

Human biomonitoring or biological monitoring refers to the systematic sampling of body fluids (e.g., blood, urine, exhaled air), and at times body tissues, for the purpose of estimating an individual's internal dose from exposure to chemicals in the workplace or in the general environment (Paustenbach and Galbraith, 2006; Manno and Viau, 2010). Biomonitoring accounts for all exposure sources and routes (oral, dermal, and inhalation), individual differences in toxicant absorption and disposition, and critical personal or lifestyle variables, such as body size and composition, workload that affects pulmonary ventilation, or cigarette smoking that could affect the metabolic status of an individual. Although biomonitoring provides a measure of internal exposure, in the final analysis the data obtained must be relatable to the health guidance values, point of departure underlying such values or health risks. For each chemical of concern, it is useful to establish a reference biomonitoring value below which a reasonable assurance of safety exists. In this regard, the tools for interpreting biomonitoring data make use of forward dosimetry or reverse dosimetry approaches (Clewell et al., 2008; Gurusankar et al., 2017). Forward dosimetry refers to the use of toxicokinetic data and models to develop concentrations of exposure biomarkers corresponding to the existing health guidance values (e.g., occupational exposure limit, reference dose, tolerable daily intake) or point of departure in a dose–response curve (e.g., NOAEL). Well-known examples of the use of the concept of forward dosimetry in human biomonitoring include the development of (i) biological exposure indices (BEIs) by the American Conference of Governmental Industrial Hygienists (ACGIH), (ii) biological tolerance values (BATs) and biological guidance values (BLW) by the German MAK Commission, as well as (iii) biological monitoring equivalents associated with exposure guidance values or the underlying point of departure values (BE, BE_{POD}) for environmental chemicals (Hays et al., 2007; Angerer et al., 2011; Gurusankar et al., 2017). Reverse dosimetry, in contrast, involves the use of toxicokinetic parameters and models to reconstruct or estimate exposure levels associated with the measured concentrations in biomarkers in biological matrices (urine, blood, plasma, exhaled air).

Forward Dosimetry In order to compare the human biomonitoring data for environmental chemicals with reference values for the general population, the forward dosimetry approaches are useful in converting the exposure guidance value or the point of departure (POD such as NOAEL) underlying the guidance values in terms of biomarker concentrations (Aylward et al., 2013; St-Amand et al., 2014). For example, the $BE_{POD,}$ corresponding to steady-state plasma concentration for triclosan (3 mg/L) was derived from the human-equivalent POD (POD_{HED}) of 3 mg/kg/day from a study in baboons and CL = 0.98 L/kg/day as follows:

$$BE_{POD}(\text{mg/L plasma}) = \frac{POD_{HED}}{CL} \tag{7-37}$$

where POD_{HED} = POD (30 mg/kg/day) divided by animal-human uncertainty factor of 10.

Following the application of the interindividual uncertainty factor of 10, plasma BE of 0.3 mg/L was obtained (Krishnan et al., 2010a, 2010b).

A forward dosimetry approach for developing urinary BE_{POD}, under chronic exposure conditions leading to steady state, involves multiplying the ingested dose with a factor representing the urinary excretion fraction (Aylward and Hays, 2008; Krishnan et al., 2010a, 2010b). On this basis, the steady-state urinary biomarker concentrations (mg/L urine and mg/g creatinine) associated with the human-equivalent PODs (BE_{POD}) are developed as follows:

$$BE_{POD}(\text{mg/L Urine}) = \frac{[POD_{HED}(\text{mg/kg/day}) \times BW(\text{kg}) \times F_{UE}]}{\text{Urine Volume (L/day)}}, \tag{7-38}$$

$$BE_{POD}(\text{mg/g Creatinine}) = \frac{[POD_{HED}(\text{mg/kg/day}) \times BW(\text{kg}) \times F_{UE}]}{\text{Creatinine (g/day)}}, \tag{7-39}$$

where BW = body weight and F_{UE} = fraction of the ingested daily dose excreted via urine

By dividing the BE_{POD} obtained with Eqs. (7-38) and (7-39) by the interindividual variability factor of 10, the BE (in units of mg/L urine and mg/g creatinine) is obtained. Thus, for bisphenol A, the urinary BE_{POD} and BE of 10 mg/L and 1 mg/L were derived from POD_{HED} of 0.25 mg/kg/day (based on rat NOAEL of 25 mg/kg/day) and F_{UE} value of 1 (i.e., 100% of the ingested dose excreted in urine) (Krishnan et al., 2010b). Similarly, for triclosan the urinary BE_{POD} and BE equal 64 mg/L and 6.4 mg/L, given that the POD_{HED} = 3 mg/kg/day (based on baboon NOAEL of 30 mg/kg/day) and the F_{UE} = 0.54 (Krishnan et al., 2010a). The BE and BE_{POD} values derived using forward dosimetry approaches inherently reflect the underlying limitations and uncertainties associated with the exposure guidance value and the toxicokinetic database used in their derivation (Hays et al., 2007).

Reverse Dosimetry Reverse dosimetry approaches use the toxicokinetic parameters or models to convert the biomarker concentration into the exposure dose. The sampling time relative to the exposure pattern would be a straightforward matter if exposure is continuous and constant, in which case blood, urine, or other samples can be collected at any time after steady state is reached. In reality, exposure is often episodic or intermittent, and in occupational settings exposure is dictated by the work shift. Systematically timed sampling is hardly feasible in a community population exposure study, where sampling is typically random, and exposure comes from diffuse sources and may not occur with any definable regularity. The only approach to overcome such shortcoming is to obtain samples at different times of a day to provide diurnal coverage, which introduces obvious logistical and cost challenges in a population surveillance program. It is not often appreciated that the observed level of a determinant for a chemical exposure is a function of not only current exposure, but also what happened some time before (Droz et al., 1991). This is particularly so when exposure is continuous or the interval between intermittent exposures is on the order of the chemical's elimination half-life (e.g., an elimination $t_{1/2}$ of 24 hours or longer when exposure reoccurs on a daily basis). In other words, the elimination half-life of a biomarker or index compound dictates how far back in exposure history it reports. A corollary to this principle is the fact that short half-life biomarkers reflect more of the within day or day-to-day fluctuation in exposure, whereas daily fluctuation in exposure is dampened with long half-life biomarkers. Although the former cases may be viewed as undesirable because of variability in the measurement, it offers a better reflection of the oscillation in internal dose and particularly the transient peak exposures. The latter cases provide a less variable, time-averaged measure of exposure.

Reverse dosimetry has been conducted using deterministic or probabilistic toxicokinetic models. The simple deterministic approaches are based on either assumption of steady-state kinetics or urinary mass-balance calculation. More sophisticated approaches use the classic compartmental and physiological models described in the previous sections to perform the back-calculations for various scenarios, routes, and populations (Clewell et al., 2008; Georgopoulos et al., 2009).

An example of the application of reverse dosimetry at steady-state condition involves the calculation of the daily dose absorbed (mg/kg/day) from measured blood concentration at steady state (mg/L) as well as K_{el} (day^{-1}) and V_d (L blood/kg) as follows (NRC, 2006):

$$D_{abs} = K_{el} \times V_d \times C_{b,ss}. \tag{7-40}$$

Similarly, back-calculation of daily dose to which exposure has occurred can be conducted as follows, based on measured urinary concentration:

$$\text{Daily intake(mg/kg/day)} = \frac{C_{urine} \times V_{urine}}{\text{Body weight} \times F_{UE}}. \tag{7-41}$$

It is relevant to note that the urinary excretion rate (dU_B/dt) of a biomarker is related to its concentration in blood or plasma concentration (C) by renal clearance (Cl_r) as follows:

$$\frac{dU_B}{dt} = Cl_r \cdot C. \tag{7-42}$$

In the above equation, dU_B/dt represents an average urinary excretion over a relatively short collection interval; C is the blood or plasma concentration at the mid-time point. The differential form of Eq. (7-42) can be integrated over an extended collection period, say 24 hours, to yield a relationship between the total amount excreted in the collection period ($U_{B,24}$) and the corresponding area under the blood or plasma concentration–time curve (AUC_{0-24}, an integral measure of exposure):

$$U_{B,24h} = Cl_r \cdot AUC_{0-24}. \tag{7-43}$$

Hence, either excretion rate or cumulative excretion over a defined collection period of a urinary biomarker is the most appropriate index secondary to blood concentration measurement. Urinary excretion rate is in turn related to pooled urine concentration ($C_{UB,\Delta t}$) and urinary flow rate ($V_{\Delta t}/\Delta t$).

$$\frac{dU_B}{dt} = C_{UB,\Delta t} \cdot \left(\frac{V_{\Delta t}}{\Delta t}\right). \tag{7-44}$$

Urinary concentration as measured from spot collection offers convenience and flexibility; however, it has the distinct disadvantage of being influenced by urine flow rate, which varies greatly from time to time depending on the hydration state of the individual. Several methods have been proposed to adjust for variation in urine flow rate. Urinary creatinine is most often used to normalize urinary concentration data. The following equation shows one such normalization (e.g., Garde et al., 2004):

$$U_{B,24} = \left(\frac{C_{UB}}{C_{UCr}}\right) \cdot U_{Cr,24}, \tag{7-45}$$

where C_{UB} and C_{UCr} are the respective biomarker and creatinine concentration in the spot urine collection, and $U_{Cr,24}$ is the daily urinary output of creatinine. This method assumes that blood concentration of biomarker is reasonably constant throughout the day (e.g., during stable, continuous exposure or for a chemical with very long elimination half-life). The daily urinary output of creatinine is assumed to be constant between individuals; alternately, it can also be adjusted according to individual variables that are known to affect creatinine production such as body mass, age, and sex (Boeniger et al., 1993).

An alternate, more commonly adopted normalization is to simply express the amount of biomarker in the spot urine collection per mmol of creatinine. This simple normalization is valid for spot urine collection if we assume creatinine excretion is constant throughout the day and reproducible from individual to individual, which are often not true. It is not surprising that validity of normalizing urinary biomarker to per mmol creatinine has been questioned (Boeniger et al., 1993). Other normalization methods including adjustment to a standard urine flow rate, specific gravity, or osmolality have also been proposed (Hill et al., 1988; Boeniger et al., 1993; Gurusankar et al., 2017).

CONCLUSIONS

Toxicokinetic data and models are central to the selection of doses and species for toxicity testing, interpretation of dose–response relationships, and efficient design of experiments for focused and reduced animal use. The toxicokinetic principles are also key to the design and interpretation of human biological monitoring studies as established in occupational health research for many decades and more recently in screening level risk assessment of environmental pollutants. The emerging toxicity testing and risk assessment paradigms as well as the extensive ongoing human biomonitoring programs will require toxicokinetic data and tools for a large number of chemicals. In this regard, increasing focus on the development of high throughput (HTP) approaches to derive toxicokinetic

parameters and PBPK models for new chemicals, mixtures, and particles is required. So far, there have been few successful attempts to integrate in vitro data and quantitative structure-property relationships for partition coefficients within the PBPK framework to simulate the inhalation toxicokinetics of chemicals (Peyret and Krishnan, 2011; Bessems et al., 2014). Further, there has been successful application of the HTP data on plasma protein binding (equilibrium dialysis) and intrinsic clearance (cryopreserved hepatocytes) to generate steady-state concentrations for the oral route, to facilitate the conversion of HTP toxicity study results into daily doses in humans (Wetmore et al., 2013; Wetmore, 2015). The emerging toxicity testing and risk assessment paradigms require HTP in vitro and in silico approaches that have broad capability and application domains in terms of chemical space, exposure route, and toxicokinetic parameters. In addition, advances in the development of physiologically based cellular toxicokinetic models will facilitate simulations of dose metrics at macro and micro levels to better understand the relationship among the concentrations of chemicals causing perturbations in HTP screening assays, levels of chemicals and their metabolites found in population level biomonitoring studies, as well as the human exposure guidance values.

ACKNOWLEDGEMENTS

The author would like to thank Ms Chantal Bellefeuille of IRSST and Siva Ramoju of Risk Sciences International for their valuable assistance with the preparation of this chapter. The editor and author acknowledge Michele A. Medinsky and Curtis Klaassen (fifth edition), Michele A. Medinsky and John L. Valentine (6th edition), and Danny D. Shen (7th and 8th editions) as previous authors of this chapter, from which some materials are reproduced.

OVERVIEW

Cancer is a disease characterized by genomic mutation, modified gene expression, cell proliferation, and aberrant cell growth. It ranks as one of the leading causes of death in the world. In the United States, cancer ranks as the second leading cause of death, with over 1.68 million new cases of cancer diagnosed and more than 0.6 million Americans dying from cancer annually (Siegel et al., 2016). Multiple causes of cancer have been established including infectious agents, radiation, and chemicals. Estimates suggest that 70% to 90% of all human cancers have a linkage to environmental, dietary, and behavioral factors (Fig. 8-1). Although our understanding of the biology of the progression from a normal cell to a malignant one has advanced considerably in the past several decades, many aspects of the cause, prevention, and treatment of human cancer and in particular the influence of lifestyle remain to be completely resolved.

Definitions

An understanding of the cellular and molecular aspects of the cancer process requires an understanding of the scientific terms involved in defining and describing the pathology of neoplasia (Table 8-1). Neoplasia is defined as new growth or autonomous growth of tissue. A neoplastic lesion is referred to as a neoplasm. A neoplasm can be either benign or malignant. Both types of lesions are induced by chemical carcinogens. Benign neoplasms (e.g., adenomas) are lesions characterized by expansive growth, frequently exhibiting slow rates of proliferation that do not invade

Table 8-1
Terminology

Neoplasia	New growth or autonomous growth of tissue
Neoplasm	The lesion resulting from the neoplasia
Benign	Lesions characterized by expansive growth, frequently exhibiting slow rates of proliferation that do not invade surrounding tissues
Malignant	Lesions demonstrating invasive growth, capable of metastases to other tissues and organs
Metastases	Secondary growths derived from a primary malignant neoplasm
Tumor	Lesion characterized by swelling or increase in size, may or may not be neoplastic
Cancer	Malignant neoplasm
Carcinogen	A physical or chemical agent that causes or induces neoplasia
Genotoxic	Carcinogens that interact with DNA resulting in mutation
Non-genotoxic	Carcinogens that modify gene expression but do not damage DNA

surrounding tissue or other organs. Benign neoplasms can impair and damage the normal function of an organ through its growth by impeding blood flow. A malignant neoplasm (e.g., a carcinoma) demonstrates invasive growth characteristics, capable of spreading not only through the organ of origin but also via metastasis to other organs. Metastases are secondary growths derived from the cells of the primary malignant neoplasm.

The term tumor is a general term that is frequently used synonymous with a neoplastic lesion and describes a grossly visible lesion. Further histopathological examination is required to confirm exact type, grade, and stage of the neoplasm. In classifying neoplasms, the nomenclature reflects both the tissue or cell of origin, and the characteristics of the type of tissue involved (Table 8-2). For benign neoplasms, the tissue of origin is frequently followed by the suffix "oma"; for example, a benign fibrous neoplasm would be termed fibroma, and a benign glandular epithelium termed an adenoma. Malignant neoplasms from epithelial origin are called carcinomas (from which the term cancer has evolved) while those derived from mesenchymal origin are referred to as sarcoma. Thus, a malignant neoplasm of fibrous tissue would be a fibrosarcoma while that derived from bone would be an osteosarcoma. Similarly, a malignant neoplasm from the liver would be a hepatocellular carcinoma while that derived from skin squamous epithelium is referred to as a squamous cell carcinoma. Preneoplastic lesions have also been observed in a number of target organs of both animal models and humans, and reflect an early reversible lesion in neoplasm progression. The characterization and study of preneoplastic cells have led to further understanding of the process of cancer formation.

The term cancer describes a subset of neoplasia that represents malignant neoplasms. A carcinogen is an agent, chemical or physical or biological (viruses), that causes or induces a cancer, although it is often also used to describe an agent that produces benign neoplastic lesions in rodent bioassays. In regulatory science this has been further defined as an agent whose administration to previously untreated animals leads to a statistically significant increased incidence of neoplasia of one of more histogenetic types as compared with the incidence seen in untreated control animals (Pitot, 1986). Thus, the induction of either or both benign and malignant neoplasms by a chemical or physical agent is included in the definition of a carcinogen. Carcinogens can be chemicals, viruses, hormones, radiation, or solid materials. Carcinogens either produce new neoplastic growth in a tissue or organ or increase the incidence and/or multiplicity of background spontaneous neoplastic formation in the target tissue.

Table 8-2
Neoplasm Nomenclature

TISSUE OF ORIGIN	BENIGN NEOPLASM	MALIGNANT NEOPLASM
Connective tissue		
Bone	Osteoma	Osteosarcoma
Fibrous	Fibroma	Fibrosarcoma
Fat lipid	Lipoma	Liposarcoma
Blood cells and related cells		
Hematopoietic cells		Leukemias
Lymphoid tissue		Lymphomas
Muscle		
Smooth	Leiomyoma	Leiomyosarcoma
Striated	Rhabdomyoma	Rhabdomyosarcoma
Endothelium	Hemangioma	Angiosarcoma
Mesothelium		Mesothelioma
Epithelial		
Squamous	Squamous cell papilloma	Squamous cell or carcinoma
Respiratory	Bronchial adenoma	Bronchogenic carcinoma
Renal epithelium	Renal tubular adenoma	Renal cell carcinoma
Liver cells	Liver cell adenoma	Hepatocellular carcinoma
Urinary epithelium	Transitional cell papilloma	Transitional cell carcinoma
Testicular epithelium		Seminoma
Melanocytes		Malignant melanoma

Table 8-3
Features of Genotoxic and Non-genotoxic Carcinogens

Genotoxic carcinogens
- Mutagenic
- Can be complete carcinogens
- Tumorigenicity is dose responsive
- No theoretical threshold

Non-genotoxic carcinogens
- Nonmutagenic
- Threshold, reversible
- Tumorigenicity is dose responsive
- May function at tumor promotion stage
- No direct DNA damage
- Species, strain, tissue specificity

The process of carcinogenesis is a multistage and multistep process involving modification and mutation to genes that regulate important normal cellular processes. An extensive literature base exists to describe the changes that cells undergo during the formation of neoplasia. Characteristics of cancers and the biological processes involved have been extensively reviewed (Hanahan and Weinberg, 2011). For the purpose of regulatory classification, carcinogens have frequently been divided simplistically into two major categories based on their general mode of action: genotoxic and non-genotoxic. Genotoxic carcinogens are those agents that interact with DNA to damage or change its structure. They are frequently mutagenic in a dose-responsive manner, and for regulatory purposes they are classified as exhibiting low-dose linear patterns, which approximates a straight line at very low doses without a threshold and a lack of reversibility of effect upon removal of the agent.

Non-genotoxic carcinogens are the agents that do not directly interact with nuclear DNA. Non-genotoxic carcinogens may change gene expression, modify normal cell function, bind to or modify cellular receptors, and increase the number of cells in the target tissue. These agents work through epigenetic mechanisms that modify DNA and proteins associated with DNA which alter the gene expression or the cellular phenotype without modifying or directly damaging its structure. Non-genotoxic chemical carcinogens create a situation in a cell or tissue that makes it more susceptible to DNA damage from other sources (natural or xenobiotic), which in turn may increase the rate of mutagenesis and thus carcinogenesis. Non-genotoxic agents for regulatory purposes exhibit a nonlinear, threshold, and dose–response pattern in their carcinogenicity. Common features of genotoxic and non-genotoxic carcinogens are shown in Table 8-3.

For regulatory purposes, several attempts have been made to characterize chemical carcinogens based on cellular and molecular pathways that are perturbed following agent exposure. Smith and associates have compiled a list of 10 key effects (Table 8-4) of carcinogens in an effort to use established mode of action data to help assess the potential carcinogenicity of untested agents (Smith et al., 2016). This builds on the mode of action framework (Sonich-Mullin et al., 2001; Cohen et al., 2003; Boobis et al., 2006). As with all approaches to characterizing, identifying, and evaluating mechanistic data when assessing whether an agent is a potential human carcinogen, it is important to consider dose–response and adverse versus adaptive changes from the experimental data. In addition, one should be cognizant of the interaction and multiplicity of pathways in the cancer process. For example increased inflammation results in oxidative stress and damage that can in turn induce epigenetic changes including increased cell number.

HISTORICAL BACKGROUND

A historical foundation for the linkage of the induction of cancer in humans and animal models by chemicals has been well documented (Table 8-5). Several excellent reviews of the historical background of carcinogenesis and cancer research have been published (Shimkin, 1980; Diamandopoulos, 1996; Creech, 2000; Harvey, 2011). Studies over the last three centuries on chemically induced cancer are marked initially by epidemiological observations followed by experimental studies involving animal carcinogenesis models.

In 1775, Percival Pott described a linkage between the increased occurrence of scrotal and nasal cancer among chimney sweeps and their occupation. Pott concluded that chimney soot was the causative agent for cancer induction in these individuals (Pott, 1775). Other investigators also recognized an association between exposure

Table 8-4

Key Characteristics of Carcinogens

CHARACTERISTIC	EXAMPLES OF RELEVANT EVIDENCE
1. Is electrophilic or can be metabolically activated	Parent compound or metabolite with an electrophilic structure (e.g., epoxide, quinone), formation of DNA and protein adducts
2. Is genotoxic	DNA damage (DNA strand breaks, DNA–protein cross-links, unscheduled DNA synthesis), intercalation, gene mutations, cytogenetic changes (e.g., chromosome aberrations, micronuclei)
3. Alters DNA repair or causes genomic instability	Alterations of DNA replication or repair (e.g., topoisomerase II, base-excision or double-strand break repair)
4. Induces epigenetic alterations	DNA methylation, histone modification, microRNA expression
5. Induces oxidative stress	Oxygen radicals, oxidative stress, oxidative damage to macromolecules (e.g., DNA, lipids)
6. Induces chronic inflammation	Elevated white blood cells, myeloperoxidase activity, altered cytokine, and/or chemokine production
7. Is immunosuppressive	Decreased immunosurveillance, immune system dysfunction
8. Modulates receptor-mediated effects	Receptor in/activation (e.g., ER, PPAR, AhR) or modulation of endogenous ligands (including hormones)
9. Causes immortalization	Inhibition of senescence, cell transformation
10. Alters cell proliferation, cell death, or nutrient supply	Increased proliferation, decreased apoptosis, changes in growth factors, energetics and signaling pathways related to cellular replication or cell cycle control, angiogenesis

Abbreviations: AhR, aryl hydrocarbon receptor; ER, estrogen receptor; PPAR, peroxisome proliferator–activated receptor.
Any of the 10 characteristics in this table could interact with any other (e.g., oxidative stress, DNA damage, and chronic inflammation), which when combined provides stronger evidence for a cancer mechanism than would oxidative stress alone.

to chemicals and the induction of human cancer. Thiersch (1875) described a relationship between sunlight exposure and skin cancer in humans. A linkage between an increased incidence of lung cancer and uranium mining was detected (Harting and Hesse, 1879). Butlin, in a follow-up of the Potts' observations, noted that scrotal cancer in chimney sweeps in the European continent was relatively rare on the continent compared to that seen in England (Butlin, 1892). He attributed this difference to better hygiene practices by the European sweeps as well as to the use of younger boys in England, suggesting that age of exposure and the duration of exposure influence the formation of the cancer. In 1895, Rehn reported a linkage between the manufacturer of aniline dyes and the induction of bladder cancer in dye workers (Rehn, 1895). Due to the increase in demand for synthetic dyes in the 19th century, production of the aniline-based dyes increased, as did the development of skin and bladder cancer in exposed workers. The specific chemicals in the dyes related to the cause of skin and bladder cancer were later determined to be the aromatic compounds 2-naphthylamine and benzidine (Hueper et al., 1938). Exposure of workers to metals, such as chromium (Alwens and Jonas, 1938) and asbestos (Wood and Gloyne, 1934), was shown to be associated with an increased incidence of lung cancers in workers. Tobacco use and its linkage to lung cancer provide an excellent case study on the linkage between epidemiology and experimental carcinogenesis. As early as 1912, Adler noted an association between smokers and lung cancer (Spiro and Silvestri, 2005). Similarly, Lickint reported on the linkage between tobacco smoking and lung cancer in the 1920s and also associated the higher rate of lung cancer seen in males with tobacco smoking (Proctor, 2001). Subsequent investigations led to the observation by Doll and colleagues, in a longitudinal epidemiology study, that there was a direct cause and effect of smoking to lung cancer (Doll et al., 2004).

Based on the epidemiological observations in humans, experimental investigations starting in the first half of the 20th century were performed to understand the biological mechanisms, nature of these chemical mixtures, and individual chemical compounds in the mixtures using animal models. Initial studies by Yamagiwa and co-workers examined the linkage between exposure to coal tar and its derivatives on cancer induction in humans by painting with coal tar on rabbit ears, which resulted in the formation of skin cancer (Yamagiwa and Ichikawa, 1915). Subsequently, Kennaway and Hieger purified dibenz(*a*,*h*)anthracene from this coal tar extract, and determined that it was at least one of the components of the coal tar mixture that was responsible for inducing skin cancer (Kennaway and Hieger, 1930). Cook et al. (1933) similarly extracted another polyaromatic hydrocarbon (PAH), benzo(*a*)pyrene, from the coal tar and showed this to also function as a carcinogen in rodents. In similar approaches with aromatic amines, Hueper and colleagues reported that 2-naphthylamine induced bladder tumors in dogs (Hueper et al., 1938), and Yoshida (1933) and Kinosita (1936) found that feeding aminoazotoluene or aminoazobenzene to rodents induced liver cancer. James and Elizabeth Miller (and their students) in the last half of the 20th century established the role of chemical structure and metabolism in the "activation" of carcinogens to a macromolecular interactive form (Miller, 1951; Miller and Miller, 1981; Miller et al., 1983). Studies with the aromatic amine compounds in animal models correlated with the human epidemiological studies that had revealed an association between bladder cancer in humans and exposure to aniline dyes in

1956	Doll and Hill	Lung cancer and other causes of death in relation to smoking

the occupational setting, and helped to define the specific chemicals in the dyes responsible for the cancer induction. Studies by investigators such as Harris and colleagues over the last 30 years have utilized the laboratory to examine the environmentally induced cancers reported in epidemiological finding, especially in the area of lung cancer and tobacco smoking (Greenblatt et al., 1994). These epidemiological and experimental studies have shown a clear correlation between the induction of cancer in humans and rodents by chemical exposure.

An important historical event in the development of carcinogenesis testing was the development of a short-term bacterial-based mutagenesis bioassay in the early 1970s by Ames and colleagues. This Salmonella-based assay has become a stalwart in the early detection of mutagenic compounds that have the potential to be carcinogenic. A recent review of the historical aspects of the development and use of the Salmonella assay has been published (Claxton et al., 2010). The success of the Ames Salmonella Assay spurred the use of in vitro assays for mutagenicity in bacteria and mammalian cells as predictors of potential rodent and human carcinogens (Tennant et al., 1987), culminating in the current genetic toxicity test battery (Eastmond et al., 2009). As we approach the third decade of the 21st century, the need to further develop high-throughput and shortened bioassays for carcinogen detection (cell or molecular biology based) has been identified (National Research Council (US) Committee on Applications of Toxicogenomic Technologies to Predictive Toxicology, 2007).

Projects within and supported by the US Federal government have been developed to address this need. These programs include the Toxicology Testing in the 21st Century (Tox 21) which is a collaboration between the National Institute of Health and the USEPA and the USEPA's Toxcast program. The latter using in vitro screening approaches coupled with computational support to help prioritize possible toxic chemicals for additional investigation. Both the Tox 21 and the Toxcast programs are new approaches to toxicity risk assessment (including cancer risk) that are founded in our current understanding of the molecular and cellular cancer-dependent pathways.

MULTISTAGE CARCINOGENESIS

Extensive experimental studies with animal models and pathological evaluation of human cancers have demonstrated that the carcinogenesis process involves a series of definable stages and steps (Shih et al., 2001; Osada and Takahashi, 2002). Operationally, three defined stages, initiation, promotion, and progression have been identified in rodent studies (initially in skin and liver tumors models) (Fig. 8-2). These steps follow a temporal sequence of events

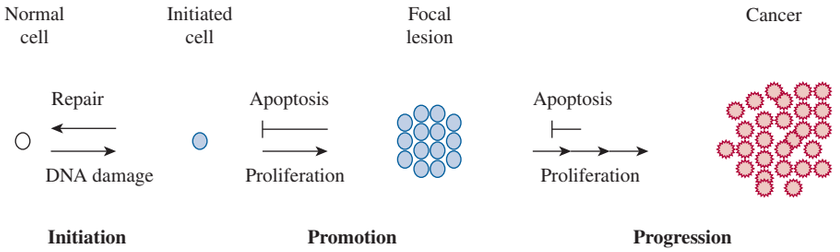

Figure 8-2. *Multistage model carcinogenesis.*

demonstrable by histopathology and observed in a wide variety of target tissues. The defining characteristics of each of these stages are outlined in Table 8-6. It is important to remember that the defining of these three stages is used to help characterize the multistage nature of chemically induce tumors. Once a neoplasm is formed, additional intracellular and extracellular changes occur in the process of the development of a malignant cancer (Goyette et al., 1992; Vogelstein and Kinzler, 2004).

Initiation

The first stage of the cancer process involves initiation, a process that is defined as a stable, heritable change. This stage is a relatively rapid, irreversible process that results in a carcinogen-induced mutational event. Chemical and physical agents that function at this stage are referred to as initiators or initiating agents. Initiating agents lead to genetic changes including mutations and deletions. Chemical carcinogens that covalently bind to DNA and form adducts that result in mutations are initiating agents. Included among chemicals classified as initiating carcinogens are compounds such as polycyclic hydrocarbons and nitrosamines, biological agents, certain viruses, and physical agents such as x-rays and ultraviolet (UV) light. Most chemical carcinogens that function at the initiation stage of the cancer process are indirect-acting genotoxic compounds that require metabolic activation in the target cell to produce the DNA-damaging event. For these compounds, the chemical must be taken into the target site and metabolized (in the case of an indirect genotoxic carcinogen). The ultimate form of the carcinogen is then able to bind to nuclear DNA, resulting in adduct formation. The initiating event becomes "fixed" when the DNA adducts or other damage to DNA is not correctly repaired or is incompletely repaired prior to DNA synthesis. This event can lead to inappropriate base pairing and formation of a mutation.

Initiation by itself does not appear to be sufficient for neoplastic formation. Once initiated cells are formed, their fate has multiple potential outcomes: (1) the initiated cell can remain in a static nondividing state through influences by growth control either via normal surrounding cells or through endocrine influence; (2) the initiated cell may possess mutations incompatible with viability or normal function and be deleted through apoptotic mechanisms; or (3) the cell, through stimuli such as intrinsic factors or from chemical exposure, may undergo cell division resulting in the growth in the proliferation of the initiated cell. Besides the production of an initiated cell through carcinogen binding and misrepair, additional evidence has come forth showing that induction of continual stress, resulting in continual cell proliferation, can also produce new mutated, initiated cells (Matthews et al., 2009; Johnstone and Baylin, 2010). Therefore, modification of cell signaling and gene expression (while usually ascribed to the tumor promotion process and as an epigenic pathway [see below]) may indirectly through sustained cell proliferation also result in the formation of mutations (Lewandowska and Bartoszek, 2011). In some instances, typically following relatively high doses and/or repeated exposure to the genotoxic carcinogen, a chemical carcinogen may function as a complete carcinogen, that is, it is capable of progressing through all stages of the cancer process.

Table 8-6

Characteristics of the Stages of Carcinogenesis Process

Initiation
DNA modification
Mutation
Genotoxic
One cell division necessary to lock-in mutation
Modification is not enough to produce cancer
Nonreversible
Single treatment can induce mutation
Promotion
No direct DNA modification
Non-genotoxic
No direct mutation
Multiple cell divisions necessary
Clonal expansion of the initiated cell population
Increase in cell proliferation or decrease in cell death (apoptosis)
Reversible
Multiple treatments (prolonged treatment) necessary
Threshold
Progression
DNA modification
Genotoxic event
Mutation, chromosome disarrangement
Changes from preneoplasia to neoplasia benign/malignant
Irreversible
Number of treatments needed with compound unknown (may require only single treatment)

Promotion

The second stage of the carcinogenesis process (the promotion stage) involves the selective clonal expansion of initiated cells to produce a preneoplastic lesion. Exogenous and endogenous agents

that function at this stage are frequently referred to as tumor promoters. Compounds that function at the promotion stage are not mutagenic and generally are not able to induce tumors by themselves. They act though mechanisms that involve changes in gene expression that in turn result in sustained cell number in the target tissue either through increases in cell proliferation and mitogenesis and/or the inhibition of apoptosis. This stage involves the modulation of gene expression through receptor or non–receptor-mediated processes. Non-genotoxic carcinogens frequently function at the tumor promotion stage. The growth of preneoplastic lesions requires repeated applications or continuous exposure to tumor-promoting compounds. Although initial exposure to tumor promoters may result in an increase in cell proliferation and/or DNA synthesis in normal cells in an organ, this is usually a transient effect. With repeated applications of the chemical only initiated cells continue to clonally expand and divide into a focal lesion (Fig. 8-2). Tumor promotion is a dose-dependent and reversible process whereby removal of the promotional agent, the focal cells cease proliferation and through apoptosis the focal lesion may return back to a small group of initiated cells. In addition, agents that function at the promotion stage demonstrate a dose-dependent threshold for their effects. Below a certain dose or frequency of application the chemical is unable to induce cell growth. Carcinogens that function at the tumor promotion stage in general are organ specific. For example, phenobarbital functions at the tumor promotion stage selectively in the liver but will not promote tumorigenesis in the skin or most other tissues.

Progression

A third stage of the chemical carcinogenesis process, progression, involves the conversion of the preneoplastic lesions to a neoplasm. In this stage, additional genotoxic events occur resulting in additional DNA damage including chromosomal damage such as aberrations and translocations. In the neoplastic state, cells accumulate mutations and epigenetic changes that release normal growth control of the cells and cause them to outgrow the surrounding normal cells. The tumor microenvironment is an important component of this process and the presence of "normal" cells and stroma within the lesion is critical for the neoplastic cells to survive and propagate. During the progression stage, the clonal nature of the neoplastic lesion is typically lost with a polyclonal appearance of cells within the lesion. Agents that impact on the progression stage are usually genotoxic agents although the acquisition of additional mutagenic events may occur through the continual stimulation of cell proliferation. These events result in the transfer from preneoplastic, clonally derived cell populations into neoplastic cell populations. By definition, the progression stage is an irreversible stage in that neoplasm formation, whether benign or malignant, occurs. With the formation of neoplasia, an autonomous growth and/or lack of growth control is achieved. Spontaneous progression can occur from spontaneous karyotypic changes that occur in mitotically active initiated cells during promotion. An accumulation of nonrandom chromosomal aberrations and karyotypic instability are hallmarks of progression. As such, chemicals that function at the progression stage of carcinogenesis many times are clastogenic and are capable of causing chromosomal abnormalities.

Complete carcinogens have the ability to function at all three stages of carcinogenesis and hence have genotoxic properties. A number of rodent and in vitro models are available to test for carcinogenicity and to study the multistep mechanisms involved in chemical carcinogenesis. These models are described below.

MECHANISMS OF ACTION OF CHEMICAL CARCINOGENS

The formation of a neoplasm is a multistage, multistep process that involves the ultimate release of the neoplastic cells from normal growth control processes and creating a tumor microenvironment. In two reviews, Hanahan and Weinberg (2000, 2011) defined the major characteristics of a neoplasm as it progresses into a malignant state. The authors have proposed eight "hallmarks of cancer" that involve modifications to the homeostasis of normal cells imparting the growth and metastatic properties seen in the development of a neoplastic cell. The eight properties include (1) sustaining cell proliferation, (2) resisting cell death (apoptosis), (3) inducing angiogenesis, (4) enabling replicative immortality, (5) activating invasion and metastasis, (6) evading growth suppressors, (7) reprogramming of energy metabolism, and (8) evading immune destruction (Table 8-7). An important concept from this review is the fact that tumors are not just a collection of clonal neoplastic cells but a complex tissue with multiple cell populations that interact with one another and function as a unique tissue. This tumor microenvironment involves the recruitment of normal stromal and inflammatory cells that contribute to the growth of the development of the neoplasm.

Although our understanding of the cancer process has expanded exponentially in the past several decades as illustrated by the "hallmarks-of-cancer" concept, in its minimalist form two major processes are needed with regard to the induction of neoplasia by chemicals: a mutational event and a selective proliferation of the mutated cell to form a neoplasm. Based on this supposition, chemicals that induce cancer have been classified into one of two broad categories (as noted above) genotoxic (DNA-reactive) agents and non-genotoxic (epigenetic) agents. This is admittedly a very simplistic approach to the complexities of the cancer process (as illustrated by the Hanahan and Weinberg's review [2011]); however, for the purposes of regulatory evaluation and cancer risk assessment this categorization has for the most part continued.

Genotoxic/DNA-Reactive Compounds

Genotoxic compounds interact with nuclear DNA of a target cell producing unrepaired DNA damage that is inherited in subsequent daughter cells. Experimental and epidemiological observations made in the middle of the 20th century identified a number of chemicals that could cause cancer in humans or experimental animals. Coal tar carcinogens including benzo(*a*)pyrene, pesticides such as 2-acetylaminofluorine, and azo dyes such as

Table 8-8

Examples of Genotoxic Carcinogens

A. Direct-acting carcinogens
- Nitrogen or sulfur mustards
- Propane sulfone
- Methyl methane sulfonate
- Ethyleneimine
- B-Propiolactone
- 1,2,3,4-Diepoxybutane
- Dimethyl sulfate
- Bis-(Chloromethyl) ether
- Dimethylcarbamyl chloride

B. Chemicals requiring activation (indirect-acting carcinogens)
- Polycyclic aromatic hydrocarbons and heterocyclic aromatics
- Aromatic amines
- *N*-Nitrosoamines
- Azo dyes
- Hydrazines
- Cycasin
- Safrole
- Chlorinated hydrocarbons
- Aflatoxin
- Mycotoxin
- Pyrrolizidine alkaloids
- Bracken fern
- Carbamates

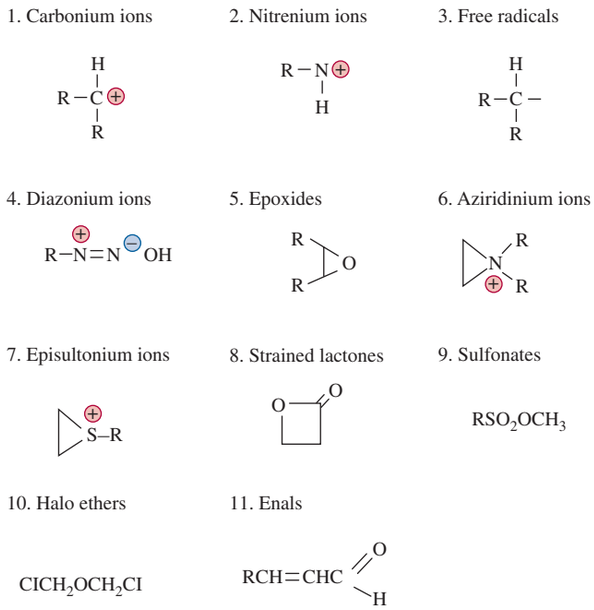

Figure 8-3. *Structures of reactive electrophiles.*

diaminobenzamide were among the first chemical carcinogens to be studied. DNA-reactive carcinogens can be further subdivided according to whether they are active in their parent form (i.e., direct-acting: chemicals that can directly bind to DNA without being metabolized) and those that require metabolic activation (i.e., indirect-acting carcinogens: compounds that require metabolism in order to react with DNA). Examples of direct-acting and indirect-acting carcinogens are listed in Table 8-8.

Direct-Acting (Activation-Independent) Carcinogens A class of carcinogens that do not require metabolic activation or modification to induce cancer are termed direct-acting or activation-independent carcinogens. These chemicals are also defined as ultimate carcinogens. Examination of the chemical structure of these chemicals reveals that they are highly reactive electrophilic molecules that can interact with and bind to nucleophiles such as cellular macromolecules including DNA. Some common electrophilic species in these groups are shown in Fig. 8-3. Generally, these chemicals containing these moieties frequently cause tumor formation at the site of chemical exposure.

Direct-acting carcinogens include epoxides, imines, alkyl and sulfate esters, and mustard gases (Fox and Scott, 1980; Sontag, 1981). Direct-acting electrophilic carcinogenic chemicals typically test positive in the Ames test without additional bioactivation with a liver metabolic fraction. The relative carcinogenic strength of direct-acting carcinogens depends in part on the relative rates of interaction between the chemical and genomic DNA, as well as competing reactions with the chemical and other cellular nucleophiles. The relative carcinogenic activity of direct-acting carcinogens is dependent upon such competing reactions and also on detoxification reactions. Chemical stability, transport, and membrane permeability determine the carcinogenic activity of the chemical. Direct-acting carcinogens are typically carcinogenic at multiple sites and in all species examined. A number of direct-acting alkylating chemicals, including a number of chemotherapeutic drugs, are carcinogenic in humans (Marselos and Vainio, 1991).

Indirect-Acting Genotoxic Carcinogens An important discovery in the understanding of chemical carcinogenesis came from the investigations of the Millers who established that many carcinogens are not intrinsically carcinogenic, but require metabolic activation to be carcinogenic. They demonstrated that azo dyes covalently bind to proteins in liver, leading to the conclusion that carcinogens may bind to proteins that are critical for cell growth control (Miller and Miller, 1947). Work with benzo(*a*)pyrene showed covalent binding of benzo(*a*)pyrene or the metabolites of benzo(*a*)pyrene in rodents (Miller, 1951). Subsequent investigations with other indirect-acting genotoxic carcinogens by other investigators confirmed that metabolism of the parent compound was necessary to produce a metabolite (activation) that was able to interact with DNA (Miller, 1970).

It has since been shown that the majority of DNA-reactive carcinogens are found as parent compounds, or procarcinogens. Procarcinogens are stable chemicals that require subsequent metabolism to be carcinogenic (Miller and Miller, 1981; Weisburger and Williams, 1981; Conney, 1982; Miller et al., 1983). The terms procarcinogen, proximate carcinogen, and ultimate carcinogen have been coined to define the parent compound (procarcinogen) and its metabolite form, either intermediate (proximate carcinogen) or final (ultimate carcinogen) that reacts with DNA (Fig. 8-4). The ultimate form of the carcinogen is most likely the chemical species that results in mutation and neoplastic transformation. The ultimate form of certain carcinogenic chemicals is not known, whereas for other chemicals there may be more than one ultimate carcinogenic metabolite depending on the metabolic pathway followed. It is important to note that besides activation of the procarcinogen to a DNA-reactive form, detoxification pathways may also occur inactivating the carcinogen.

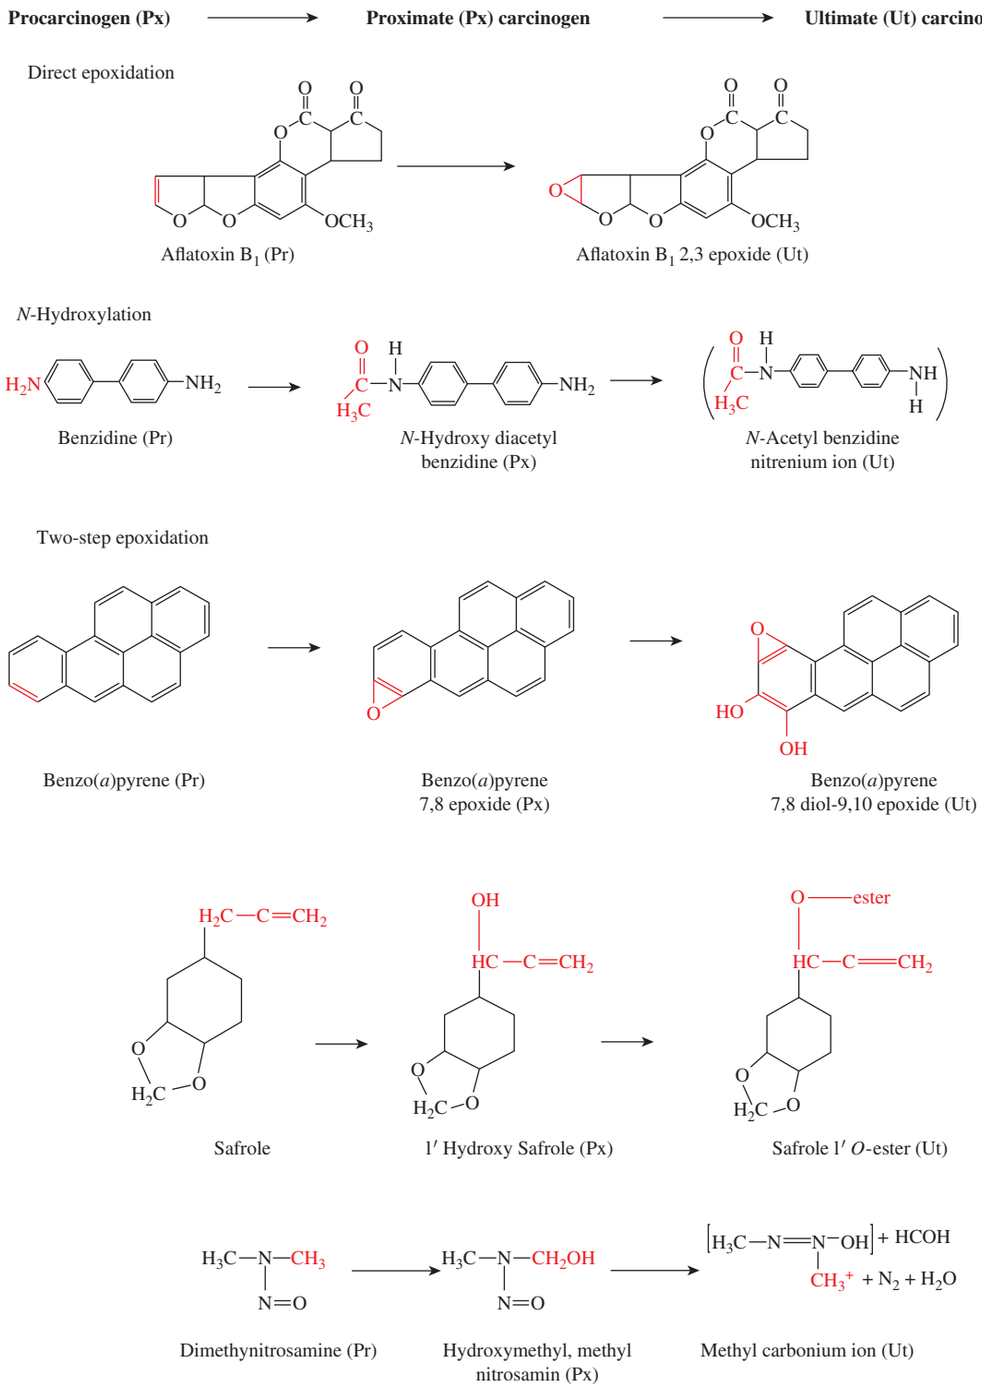

Figure 8-4. *Structures of representative indirect-acting carcinogens and their metabolic derivatives, the proximate (Px) and ultimate (Ut) carcinogenic form result from the metabolism of the procarcinogenic form (Pr).*

Indirect-acting genotoxic carcinogens usually produce their neoplastic effects, not at the site of exposure (as seen with direct-acting genotoxic carcinogens) but at the target tissue where the metabolic activation of the chemical occurs. Indirect-acting genotoxic carcinogens include the polycyclic PAHs, nitrosamines, aromatic amines, and aflatoxin B1. Fig. 8-4 shows the parent (procarcinogen) and metabolites for several representative indirect-acting genotoxic carcinogens.

Mutagenesis

The reaction of a carcinogen with genomic DNA either directly or indirectly may result in DNA adduct formation or DNA damage, and frequently produces a mutation. Several mechanisms of mutagenesis are known to occur. Modification of DNA by electrophilic carcinogens can lead to a number of products. These events are dependent upon when in the cell cycle the adducts are formed, where the adducts are formed, and the type of repair process used in response to the damage.

Transitions are a substitution of one pyrimidine by the other or one purine by the other (changes within a chemical class), whereas a transversion occurs when a purine is replaced by a pyrimidine or a pyrimidine is replaced by a purine (changes across a chemical class). Carcinogens can induce transitions and transversions several ways. In one scenario, when adducts (or apurinic or apyrimidinic sites) are encountered by the DNA replication processes, they may be misread. The polymerase may preferentially insert an adenine (A) in response to a noninformative site. Thus, the daughter strand of an A, C, G, or T adduct will have an adenine (A) and this change is fixed (mutation) and resistant to subsequent DNA repair. A second scenario, a shift in the reading frame (resulting in a frame shift mutation) may also result from carcinogen–DNA adducts formation. Most frame shift mutations are deletions and occur more frequently when the carcinogen–DNA adduct is formed on a nucleotide. In a third scenario, DNA strand breaks can also result from carcinogen–DNA adducts. These may arise either as a result of excision repair mechanisms that are incomplete during DNA replication or via direct alkylation of the phosphodiester backbone leading to backbone cleavage. Strand scission can lead to double-strand breaks, recombination, or loss of heterozygosity. It is worth noting that epigenetic changes such as altered DNA methylation, aberrant histone modifications, and dysregulated noncoding RNA expression play an important role in certain genotoxic chemicals induced carcinogenesis (Baccarelli and Bollati, 2009; Pogribny et al., 2011; Chappell et al., 2016).

Damage by Alkylating Electrophiles

As noted above, most chemical carcinogens require metabolic activation to exert a carcinogenic effect. The ultimate carcinogenic forms of these chemicals are frequently strong electrophiles (Fig. 8-3) that can readily form covalent adducts with nucleophilic targets. Because of their unpaired electrons, S:, O:, and N: atoms are nucleophilic targets of many electrophiles. The extent of adducts formed is limited by the structure of DNA where bulky electrophilic chemicals can bind, and size of the ultimate carcinogenic form. In general, the stronger electrophiles display a greater range of nucleophilic targets (i.e., they can attack weak and strong nucleophiles), whereas weak electrophiles are only capable of alkylating strong nucleophiles (e.g., S: atoms in amino acids). In addition, the metabolic capability of a target cell will dictate the extent and types of electrophiles generated from the procarcinogenic parent.

An important and abundant source of nucleophiles is contained not only in the DNA bases, but also in the phosphodiester backbone (Fig. 8-5). Although carcinogen–DNA adducts may be formed at all sites in DNA, the most common sites of alkylation include the N^7 of guanine, the N^3 of adenine, the N^1 of adenine, the N^3 of guanine, and the O^6 of guanine. Alkylations of phosphate may also occur at a high frequency. Selective examples of carcinogen interactions with proteins and nucleic acids are shown in Fig. 8-6. Different electrophilic carcinogens will often display different preferences for nucleophilic sites in DNA and different spectra of damage. Dimethylnitrosamine and diethylnitrosamine, for example, are metabolized by P450 oxidation to yield a methyl carbonium ion (CH_3^+) and an ethyl carbonium ion ($CH_3CH_3^+$), respectively. Despite the structural similarities of the ultimate electrophiles, they display significant differences in alkylation profiles (Pegg, 1984). The relative proportions of methylated bases present in DNA following reaction with carcinogen-methylating chemicals are shown in Table 8-9 (Pegg, 1984). The predominant adduct formed following exposure to methylating chemicals such as methylmethane sulfonate is 7-methylguanine. In contrast, ethylating agents produce adducts predominately in the phosphate backbone of DNA. The carcinogenic potential of the type of adducts formed is often debated; some believe that O^6-alkylguanine is the most

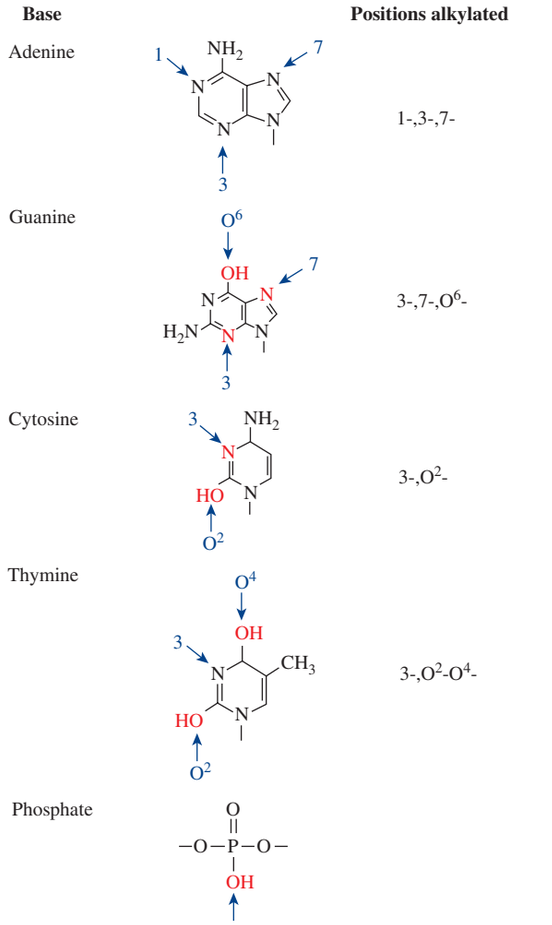

Figure 8-5. *Examples of cellular nucleophiles and sites of possible adduct formation.*

carcinogenic adduct, whereas others report that O^4-alkylthymine is more important in the carcinogenic process due to its persistence relative to other adducts (Pegg, 1984; Swenberg et al., 1984).

Another common modification to DNA is the hydroxylation of DNA bases. Oxidative DNA adducts have been identified in all four DNA bases (Fig. 8-7); however, 8-hydroxyguanine is among the most prevalent oxidative DNA adduct and an established biomarker of oxidative stress (Floyd, 1990; Valavanidis et al., 2009; Klaunig et al., 2011). The source of oxidative DNA damage is typically formed from free radical reactions that occur endogenously in the cell or from exogenous sources (Floyd, 1990; Ames and Shigenaga, 1993; Klaunig et al., 2011). Although a relatively large amount of oxidative DNA adducts have been proposed to be formed per day, repair mechanisms exist that maintain the cellular level low and keep endogenous mutations to a relatively low level. The role of oxidative damage and oxidative stress is discussed in greater detail later in this chapter.

Although a large number of adducts can be formed following exposure to chemicals, whether a particular DNA adduct will result in mutation and participate in the carcinogenesis process is dependent in part on the persistence of the adduct through the process of DNA replication, which is also in part dependent upon DNA repair.

DNA Repair

Following the formation of a carcinogen–DNA adduct, the persistence of the adduct is a major determinant of the outcome. This persistence depends on the ability of the cell to repair the altered DNA.

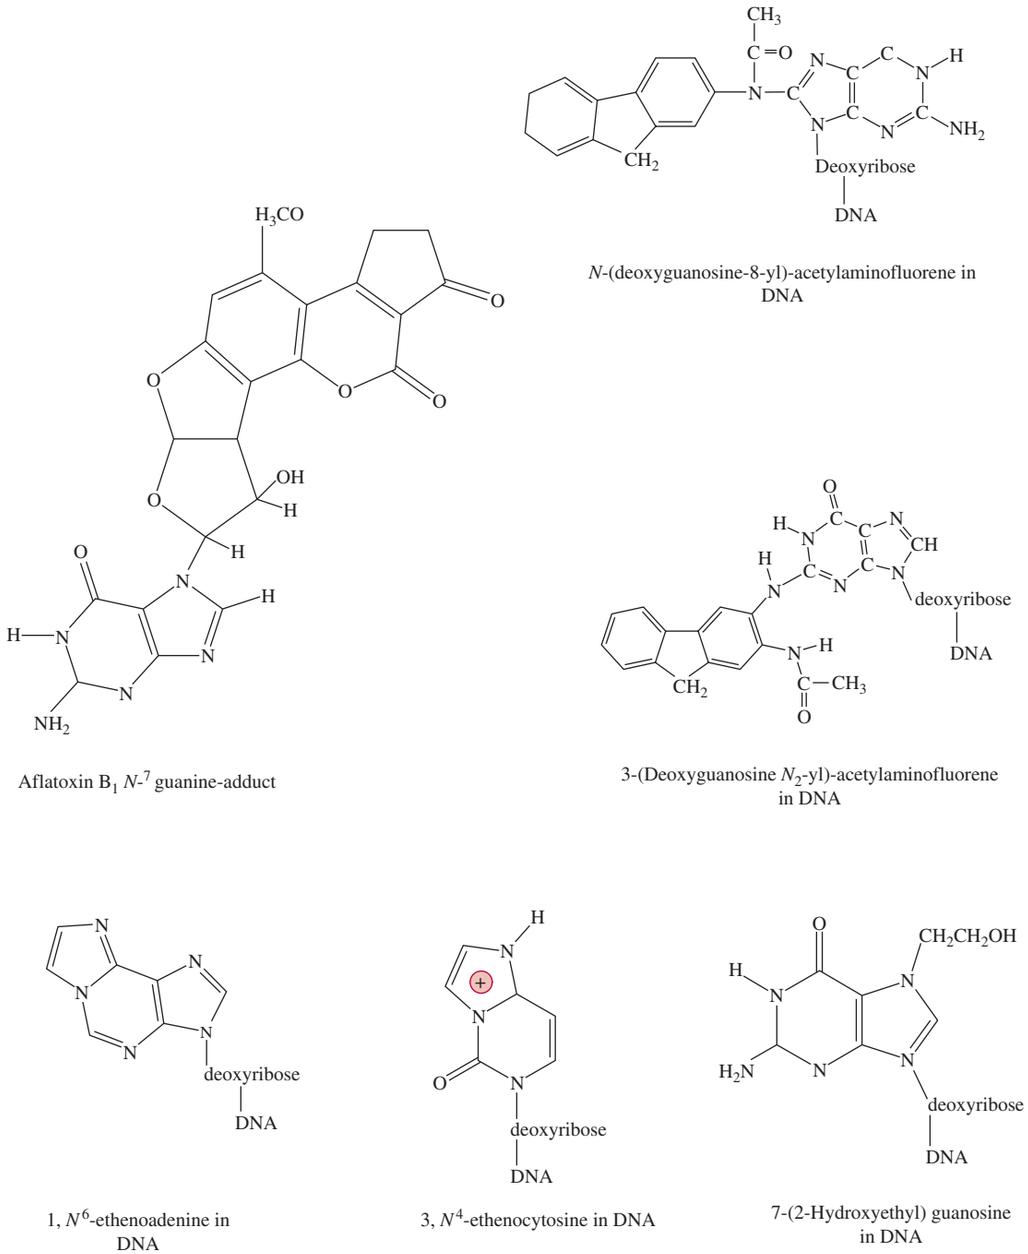

Figure 8-6. *Select structures of protein- and nucleic acid–bound forms of certain chemical carcinogens.*

The detection of unique DNA adducts has proven to be important in understanding the mechanism of action of specific carcinogens and has been correlated with carcinogenesis (Goth and Rajewsky, 1974; Kadlubar et al., 1981; Becker and Shank, 1985; Swenberg et al., 1985; Bailey et al., 1996). However, the presence of a DNA adduct is not sufficient for the carcinogenesis process to proceed. The relative rates or persistence of particular DNA adducts may be an important determinant of carcinogenicity, for example, O^4-ethylthymine is relatively stable in DNA whereas O^6-ethylguanine does not persist in DNA after continuous exposure to diethylnitrosamine (Swenberg et al., 1984). The persistence of DNA adducts of *trans*-4-aminostilbene does not correlate with organ carcinogenicity and/or tissue susceptibility. Although the liver and kidney exhibited the greatest burden and persistence of the adduct and the Zymbals gland showed the least amount of DNA adducts, the latter tissue was more susceptible to carcinogenesis by this chemical (Neumann, 1983). As such, differences in susceptibility to carcinogenesis are likely the result of a number of factors, including DNA replication within a tissue and repair of a DNA adduct.

The quantification of covalent DNA adducts in tissues has been used to demonstrate exposure of humans to carcinogenic chemicals and to assess the relative risk from exposure to carcinogenic chemicals. For example, DNA adducts of carcinogenic PAHs have been demonstrated at relatively high levels in tissues and blood of smokers and foundry workers compared with nonexposed individuals (Perera et al., 1991). In addition, DNA adducts of aflatoxin B1 were seen in samples of human placenta and cord blood in individuals in Taiwan, an area that demonstrates a high incidence of liver cancer (Hsieh and Hsieh, 1993). The presence of macromolecular carcinogen adducts may be important to their mechanism of carcinogenicity,

3-Alkylthymine	0.3	0.8
O^2-Alkylthymine	0.1	7
O^4-Alkylthymine	0.1–0.7	1–4
Alkylphosphates	12	53

the presence and persistence of the adducts is only one factor in the process of cancer development.

Experimental and epidemiological evidence indicates that the development of cancer following exposure to chemical carcinogens is a relatively rare event. This can be explained by the ability of a cell to recognize and repair DNA. The DNA region containing the adduct is removed and a new patch of DNA is synthesized, using the opposite intact strand as a template. The new DNA segment is then spliced into the DNA molecule in place of the defective one. To be effective in restoring a cell to normal, repair of DNA must occur prior to cell division; if repair is not complete prior to replication, the presence of the adducts can give rise to mispairing of bases and other genetic effects such as rearrangements and translocations of DNA segments. Thus, a chemical that alters the repair process or the rate of cell division can itself affect the frequency of mutation and neoplastic transformation.

DNA Repair Mechanisms

Although cells possess mechanisms to repair many types of DNA damage, these are not always completely effective, and residual DNA damage can lead to the insertion of an incorrect base during DNA replication, followed by transcription and translation of the mutated templates, ultimately leading to the synthesis of altered protein. Mutations in an oncogene, tumor-suppressor gene or gene that controls the cell cycle, can result in a clonal cell population with a proliferative or survival advantage. The development of a tumor requires many such events, occurring over a long period of time, and for this reason human cancer induction often takes place within the context of chronic exposure to chemical carcinogens.

A number of structural alterations may occur in DNA as a result of interaction with reactive chemicals or radiation, and the more frequent types of damage are depicted in Fig. 8-8. The reaction of chemical species with DNA can produce adducts within the bases, sugar, and phosphate backbone of DNA. In addition, bifunctional alkylating chemicals (such as mustards) may cause DNA cross-linking between two opposing bases. Other structural changes such as pyrimidine dimer formation are specific for exposure to UV light whereas double-stranded breaks in DNA are more commonly associated with ionizing radiation. A variety of mechanisms have evolved to effectively remediate and repair DNA damage. The more common types of DNA repair mechanisms seen in mammalians are listed in Table 8-10.

In addition to the proofreading activity of DNA polymerases that can correct miscopied bases during replication, cells have several mechanisms for repairing DNA damage. Repair of DNA damage does not always occur prior to cell replication, and repair of DNA damage by some chemicals is relatively inefficient. As such, exposure to chemicals can increase the probability of acquiring mutations that ultimately lead to cancer development.

Mismatch Repair of Single-Base Mispairs Spontaneous mutations may occur through normal cellular DNA replication mistakes. Many spontaneous mutations are point mutations, a change in a single base pair in the DNA sequence, or a small insertion or deletion or a frame shift mutation of some modest size. The issue for mismatch repair is determining which is the normal DNA and which is the damaged DNA strand, and, therefore, repairing the mutated strand such that the correct base pairs are restored. Depurination is a fairly common occurrence and spontaneous event in mammals, and results in the formation of apurinic sites. If these lesions are left unrepaired, mutations are generated during DNA replication as DNA synthetic machinery is unable to determine the appropriate base with which to pair. All mammalian cells possess apurinic endonucleases that function to cut DNA near apurinic sites. The cut is then extended by exonucleases, and the resulting gap repaired by DNA polymerase and ligase.

Excision Repair DNA regions containing chemically modified bases, or DNA chemical adducts, are typically repaired by

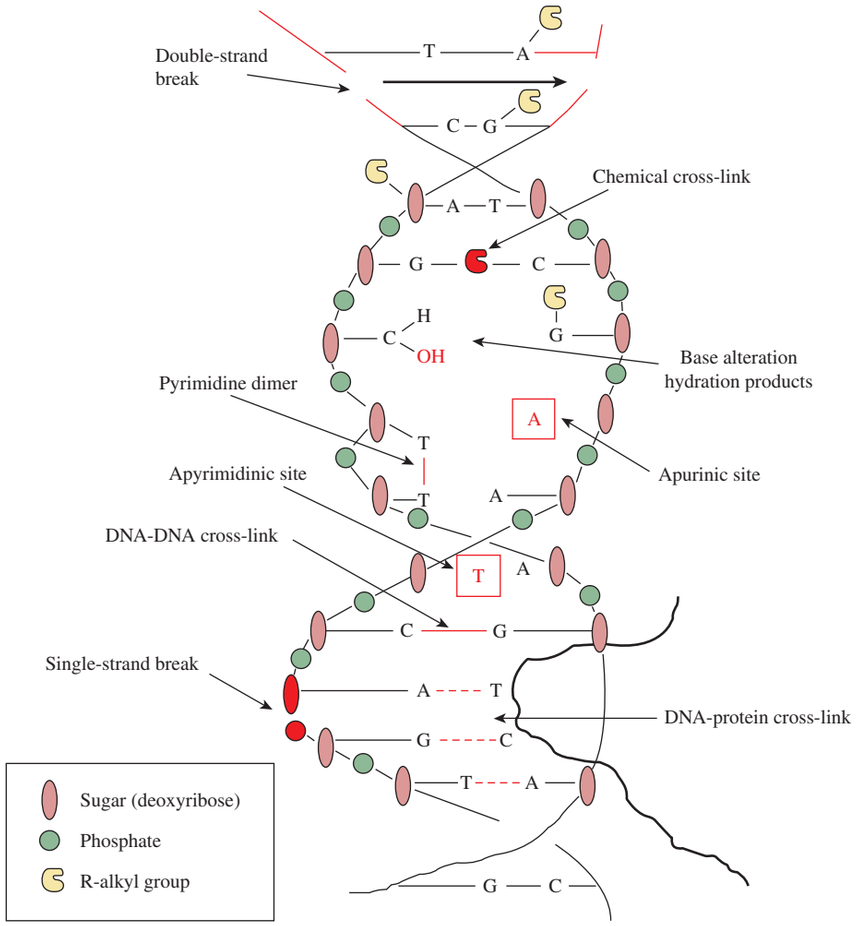

Figure 8-8. *Schematic representation of chemical and radiation-induced lesions in DNA.*

Table 8-10

DNA Repair Pathways

   - Mismatch repair (MMR)
3. Double-strand break repair
   - Homologous recombination (HR)
   - Nonhomologous end-jointing (NHEJ)

excision repair processes. DNA adducts cause a distortion in the normal shape of DNA. Proteins that slide along the surface of a double-stranded DNA molecule recognize the irregularities in the shape of the double helix, and affect the repair of the lesion. DNA lesions that are repaired by excision repair processes include thymine–thymine dimers, produced following exposure to UV light, dimers that interfere with both replication and transcription of DNA. The repair of DNA regions containing bases altered by the attachment of large chemical adducts such as benzo(*a*)pyrene are also effectively repaired by excision repair processes (Fig. 8-9A, B).

Homologous Recombination and Nonhomologous End-Joining Repair of DNA A cell that has double-strand breaks can be repaired by joining the free DNA ends. The joining of broken ends from different chromosomes, however, will lead to the translocation of DNA pieces from one chromosome to another, translocations that have the potential to enable abnormal cell growth by placing a proto-oncogene next to, and, therefore, under the control of another gene promoter. Double-strand breaks can be caused by ionizing radiation and drugs such as anticancer drugs. Double-strand breaks are correctly repaired only when the free ends of DNA rejoin exactly. The repair of double-stranded DNA is therefore confounded by the absence of single-stranded regions that can signal the correct base pairing during the rejoining process. Homologous recombination is one of two mechanisms responsible for the repair of double-strand breaks (San Filippo et al., 2008). In this process, the double-strand break on one chromosome is repaired using the information on the homologous, intact chromosome. A double-strand break of DNA that occurs in the S and G_2 phases is predominantly repaired by homologous recombination, whereas double-strand breaks formed during G_1 phase are mainly repaired via nonhomologous end joining (Branzei and Foiani, 2008).

The predominant mechanism for double-stranded DNA repair in multicellular organisms is nonhomologous repair and involves the rejoining the ends of the two DNA molecules (Lieber, 2010). Although this process yields a continuous double-stranded molecule, several base pairs are lost at the joining point. This type of deletion may produce a possibly mutagenic coding change.

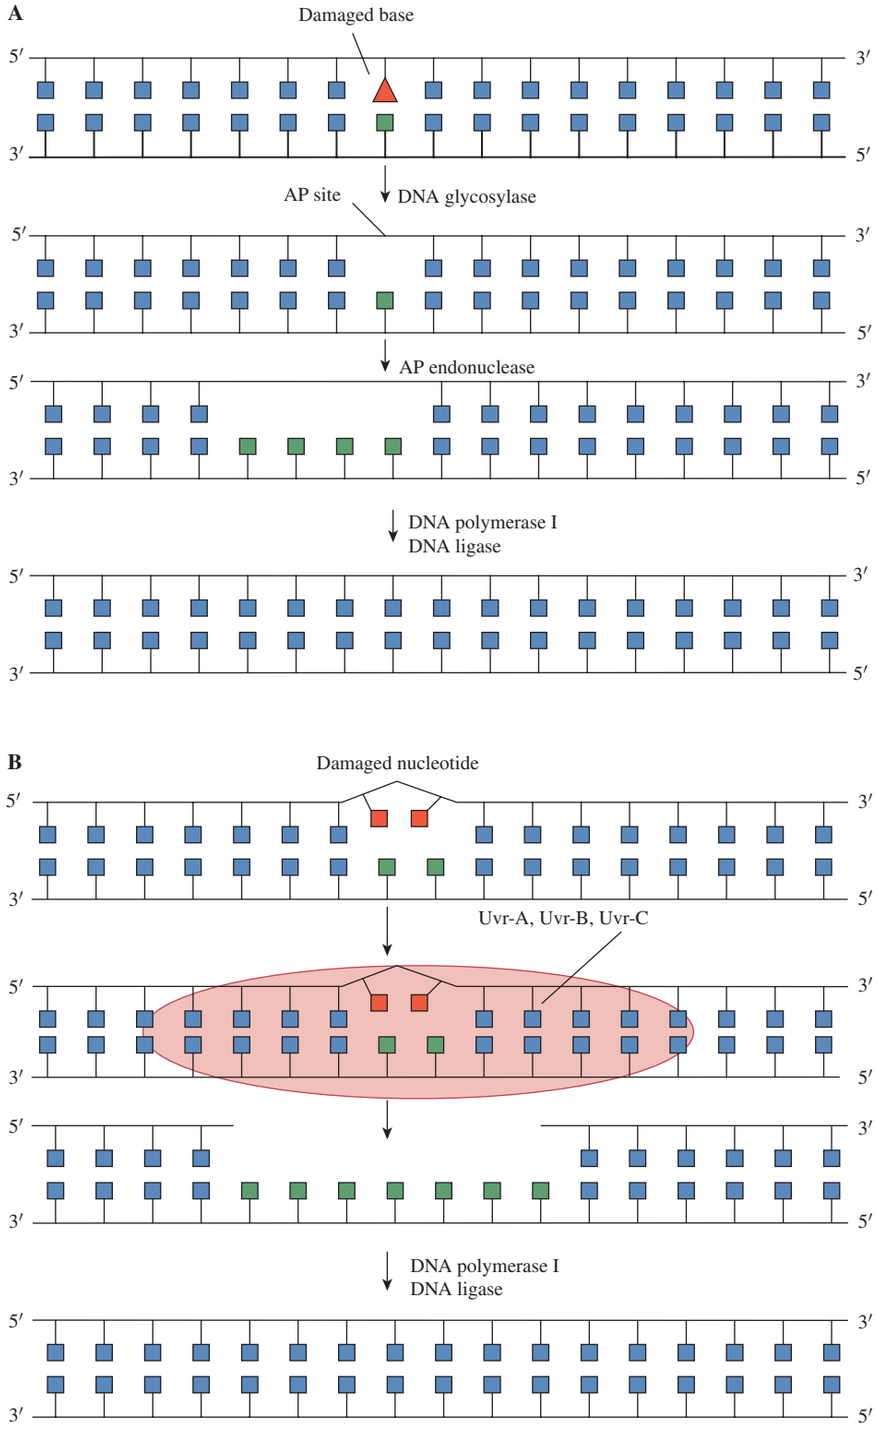

Figure 8-9. *(**A**) DNA repair by base excision. (**B**) DNA repair by nucleotide excision.*

Classes of Genotoxic Carcinogens

Polyaromatic Hydrocarbons PAHs are found at high levels in charcoal-broiled foods, cigarette smoke, and in diesel exhaust. Representative chemicals belonging to this class are shown in Fig. 8-10A. A recent review of the causes of human cancer (*120 human carcinogens*) also lists those PAHs linked to human cancer by the International Agency for Research in Cancer (IARC monographs [Vol. 100 A–F]). Benzo(*a*)pyrene is a representative polycyclic hydrocarbon that has been extensively studied. The metabolism and pathways that lead to tumor formation have been characterized through the work of a number of laboratories (Conney, 1982). The ultimate carcinogen is a diol epoxide of benzo(*a*)pyrene, formed following three separate enzymatic reactions (Sims et al.,

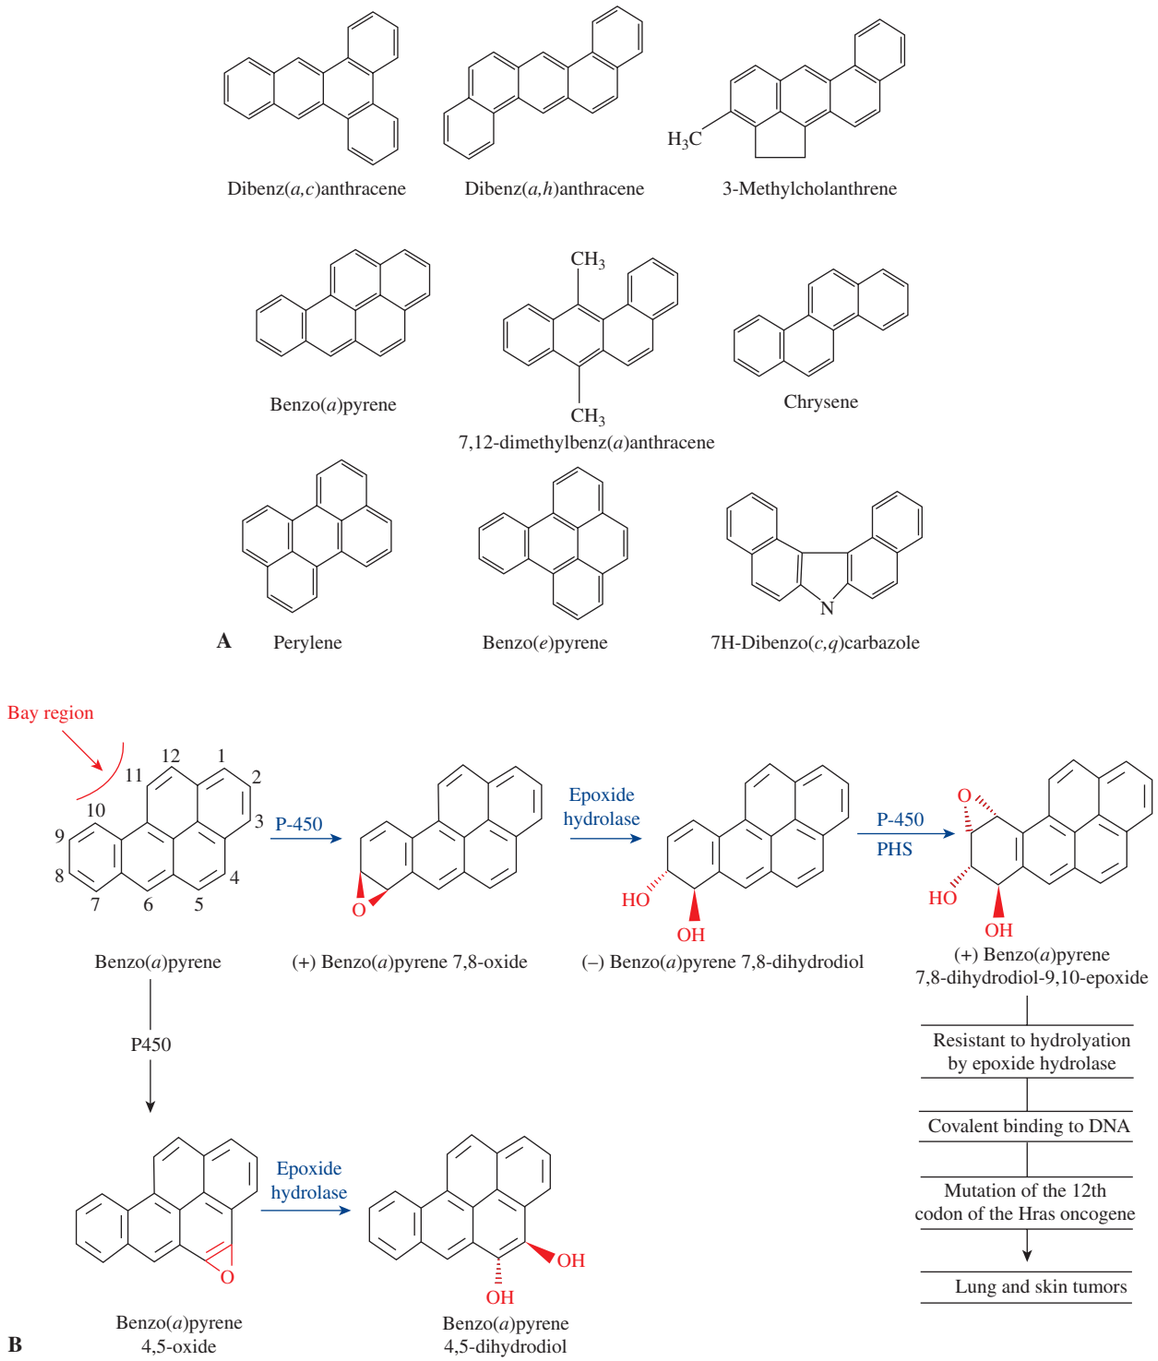

Figure 8-10. *(**A**) Chemical structures of selected carcinogenic polycyclic hydrocarbons. (**B**) Role of epoxide hydrolase in the inactivation of benzo[a]pyrene 4,5-oxide and in the conversion of benzo[a]pyrene to its tumorigenic bay region diolepoxide.*

1974). Benzo[*a*]pyrene is first oxidized by cytochrome P4501A1 to form benzo[*a*]pyrene 7,8-oxide, further metabolized by epoxide hydrolase, yielding the 7,8-dihydrodiol. And then further metabolism by cytochrome P4501A1 to yield the ultimate carcinogen, the 7,8-dihydrodiol-9,10-epoxide (Yang et al., 1976; Lowe and Silverman, 1994; Schwarz et al., 2001). The Bay region or K region of the benzo(*a*)pyrene molecule is the site of metabolic targeting and DNA interaction (Fig. 8-10B). The importance of the Bay region (K region) of the benzo(*a*)pyrene molecule was demonstrated from the understanding of the metabolism of the benzo(*a*)pyrene to its ultimate DNA-reactive form. Similar regions (to the Bay region) have been identified in other carcinogenic polycyclic hydrocarbons and used to access and predict carcinogenic potential of other PAHs. Evidence has emerged that besides the P450 metabolism pathway, PAHs can also be metabolized through a peroxidase pathway and the aldo–keto reductase (AKR) pathway. The latter of which has been attributed to

cancer risk in humans exposed to coal burning smoke in China (Lan et al., 2004). Oxidative damage-related genes AKR1C3 and oxoguanine glycosylase 2 (OGG2) also appear to modulate risks for lung cancer due to exposure to PAH-rich coal combustion emissions.

Alkylating Agents Alkylating agents represent an important class of chemical carcinogens. Although some alkylating chemicals are direct-acting genotoxic chemicals, many require metabolic activation to produce electrophilic metabolites that can react with DNA. Alkylating agents can be classified into several groups including the direct-acting alkylalkanesulfonates (methyl- and ethyl methanesulfonate) and nitrosamides (*N*-methyl-*N*-nitrosourea, *N*-ethyl-*N*-nitrosourea, *N*-methyl-*N*-nitro-*N*-nitrosoguanidine), and the indirect-acting nitrosamides (dimethyl- and diethylnitrosamines) (Fig. 8-11). The alkylating compounds (or in the case of diethylnitrosamine and dimethylnitrosamine and their metabolites) readily react with DNA at more than 12 sites. The N^7 position of guanine and the N^3 position of adenine are the most reactive sites for alkylating chemicals to bind to DNA. The reactions of DNA methylation occur more readily and thus exhibit >20 more adducts formed compared with ethylation reactions. However, ethylation reactions have a greater affinity for oxygen centers, an event that appears to correlate with the mutagenicity and carcinogenicity of these compounds. Nitrosamines were initially used as solvents in chemistry. Their toxic effects were identified when workers using the nitrosamine solvents developed jaundice and liver damage. Subsequent studies in animal models revealed that dimethylnitrosamine and, eventually, diethylnitrosamine were highly hepatotoxic and hepatocarcinogenic.

Other alkylating chemicals including the nitrogen mustards (e.g., chlorambucil, cyclophosphamide) have been used in cancer chemotherapy. They produce DNA adducts as well as induce the formation of DNA strand breaks. The alkylation of DNA by nitrogen mustards requires the formation of highly reactive *N*-alkylazirdinium ions (Fig. 8-12). Nitrogen mustards can produce a wide spectrum of mutations including base pair substitutions

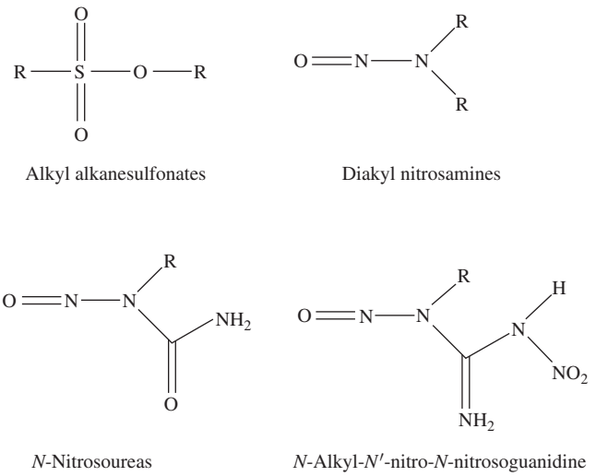

Figure 8-11. *Structures of representative methylating and ethylating agents.*

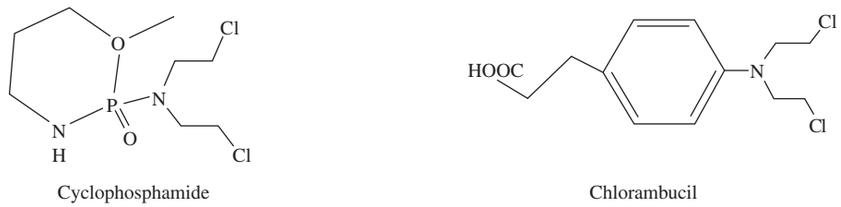

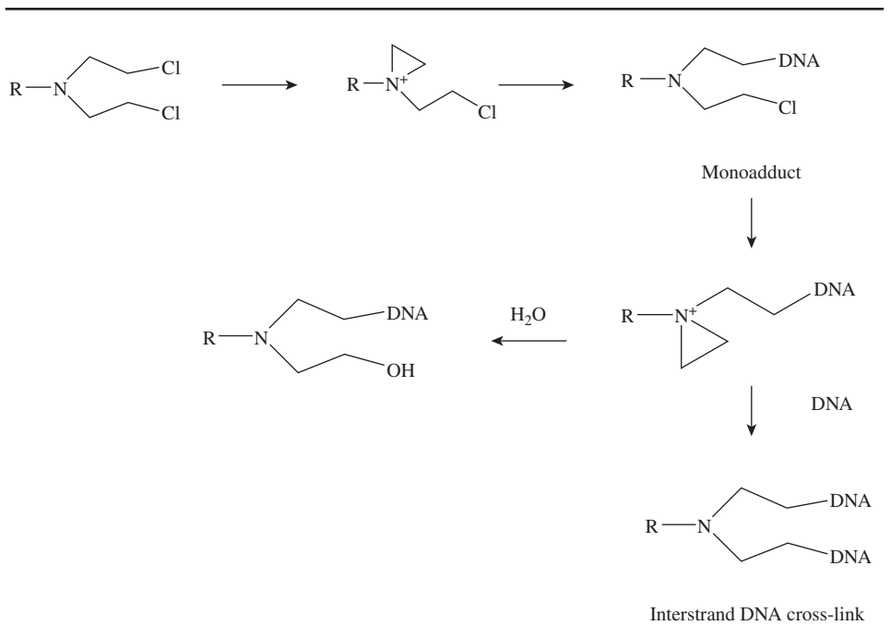

Figure 8-12. *Nitrogen mustards and proposed mechanism for the reactions of nitrogen mustards with DNA.*

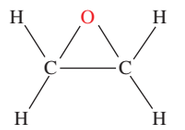
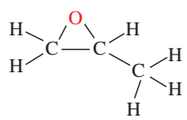
(AT and GC) and deletions. In addition, nitrogen mustards are potent clastogens causing chromosomal aberrations and sister chromatid exchanges (SCEs), predominantly in GC-rich regions.

Ethylene oxide and propylene oxide are other examples of mutagenic and carcinogenic alkylating agents (Fig. 8-13). Ethylene oxide is a direct-acting alkylating carcinogen in rodents and perhaps of human concern (Hogstedt et al., 1986). Ethylene oxide is mutagenic in short-term in vitro assays and produces chromosomal aberrations and SCEs in eukaryotic cells (Ehrenberg and Hussain, 1981). Propylene oxide is also a mutagenic rodent carcinogen inducing nasal tumors in rodents following inhalation exposure (NTP, 1985). Alkylation of DNA by ethylene and propylene oxide occurs predominantly at the N^7 position of guanine, yielding 7-(2-hydroxyethyl)guanine and 7-(2-hydroxypropyl)guanine adducts, respectively. These adducts represent the major adducts formed following either in vitro or in vivo exposure (Walker et al., 1992). In addition, both ethylene oxide and propylene oxide can form chemically stable adducts with hemoglobin, which can be used as a biomarker for exposure (Kolman et al., 2002).

Vinyl chloride is another known rodent and human carcinogen, producing angiosarcomas in the liver, increased hepatocellular carcinoma and tumors in the lung and hematopoietic system in humans (Doll, 1988; Bosetti et al., 2003; IARC, 2008). Limited evidence also suggests that vinyl chloride exposure results in brain tumors. Vinyl chloride is mutagenic and is metabolized by cytochrome P450 to form chloroethylene oxide, which rearranges nonenzymatically to produce chloroacetaldehyde, both of which can alkylate DNA. Vinyl chloride and metabolites form several DNA adducts including 7-(2′-oxoethyl)guanine, N^2, 3-etheneoguanine, 3,N^4-ethenocytosine, and 1,N^6-ethenoadenine (Guengerich, 1994). Vinyl chloride also induces an increased rate of unscheduled DNA synthesis, sister chromatid exchange, micronuclei formation, and chromosomal aberrations (IARC, 2008).



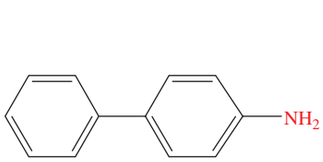
Ethylene oxide



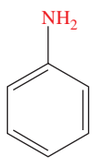
Propylene oxide

Figure 8-13. *Chemical structures for ethylene and propylene oxide.*

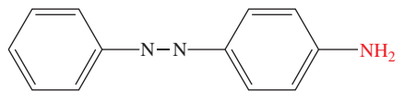
Aromatic Amines and Amides Aromatic amines and amides encompass a class of chemicals with varied structures (aromatic amines, e.g., aniline/azo dyes, 2-natphylamine, benzidine, 2-acetylaminofluofene) (Fig. 8-14). Because of their use in the dye industry and other industrial processes, their carcinogen risk to humans was realized in the late 19th century. Exposure to these chemicals still occurs through cigarette smoke and environmental sources, even though proper industrial hygiene processes have considerably reduced the human exposure to aromatic amines and amides in the workplace. The aromatic amines undergo both phase I and phase II metabolism. Phase I reactions occur mainly by cytochrome P450-mediated reactions, yielding hydroxylated metabolites that are often associated with adduct formation in proteins and DNA, and produce liver and bladder carcinogenicity (Miller et al., 1964). In addition, azo dyes can be cleaved by skin and gastrointestinal microflora into mutagenic and carcinogenic subunits (Platzek et al., 1999;



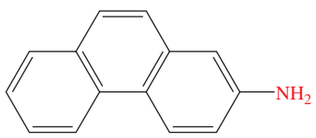
4-Aminobiphenyl (ABP)



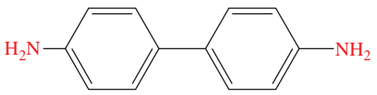
Aniline



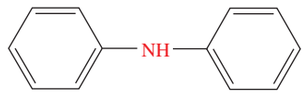
4-Aminoazobenzene



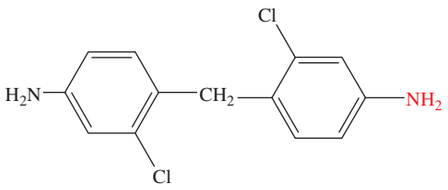
2-Aminophenanthrene



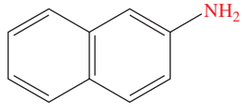
Benzidine



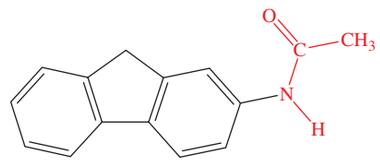
Diphenylamine



4,4′-Methylene-*bis*-2-chloroaniline



2-Naphthylamine



2-Acetylaminofluorene (2-AAF)

Figure 8-14. *Chemical structures of selected carcinogenic aromatic amines.*

Chung, 2016). Metabolism of 2-acetylaminofluorene (AAF) results in the formation of *N*-hydroxy-AAF, which is a metabolite responsible for the liver tumorigenicity. Similarly, 1-naphthylamine exhibits carcinogenic activity only in test systems capable of producing the *N*-hydroxy metabolite of naphthylamine. Aromatic amines are capable of forming adducts with several DNA bases. Both heterocyclic amines (HCAs) and PAHs are formed when muscle meat, including beef, pork, fish, and poultry, is cooked using high-temperature methods, such as pan frying or grilling directly over an open flame. HCAs are also formed from fried foods, specifically fried meats (Turesky, 2007). Mutagenic activity of cooked meats at high temperature has been reported using the Ames Salmonella mutagenesis assay. In particular, an increase in HCAs (specifically MeIQx(2-amino-3,8-dimethylimidazo[4,5-*b*]quinoxaline), DiMeIQx (2-amino-3,4,8-dimethylimidazo [4,5-*f*]quinoxaline), and IQ (2-amino-3-methylimidazo [4,5-*f*]quinolone)) was found with increasing frying temperatures and cooking duration (Knize et al., 1995). In support of these experimental studies, epidemiology linkages between consumption of high-temperature cooked foods and human cancer have been reported (Cross and Sinha, 2004; Rohrmann et al., 2007; Abid et al., 2014).

Classes and Mode of Action of Non-genotoxic (Epigenetic) Carcinogens

A number of chemicals that produce tumors in experimental animals following chronic treatment appear to act via mechanisms not involving direct binding, damage, or interaction of the chemical or its metabolites with DNA (Williams and Whysner, 1996). Based on the lack of genotoxicity, yet their ability to induce tumors in rodent models, these chemicals have been labeled non-genotoxic carcinogens. The organ and tissue targets induced by non-genotoxic carcinogens are many times in tissues where a significant incidence of background, spontaneous tumors is seen in the animal model. Prolonged exposure to relatively high levels of chemicals is usually necessary for the production of tumors by this mechanism. In addition, with non-genotoxic carcinogens, tumors are not theoretically expected to occur at exposures below a threshold at which relevant cellular effects are not observed. In contrast to DNA-reactive genotoxic effects, non–DNA-reactive mechanisms may be unique to the rodent species used for testing. Certain chemical carcinogens have been well studied and provide examples for the use of mechanistic information in risk assessment. Further, the biochemical modes of action for non–DNA-reactive carcinogens are diverse. Examples include chemicals that function via sustained cytotoxicity, receptor-mediated (e.g., CAR, peroxisome proliferator–activated receptor alpha [PPARα], aryl hydrocarbon receptor [AhR]) effects, hormonal perturbation, as well as the induction of oxidative stress and modulation of methylation status (Table 8-11). Each of these potential mechanisms is discussed in greater detail in the following sections.

Table 8-11

Proposed Modes of Action for Selected Non-genotoxic Chemical Carcinogens

MODE OF ACTOIN	EXAMPLE
Cytotoxicity	Chloroform Melamine
α2u-Globulin binding	D-Limonene 1,4-Dichlorobenzene
Receptor-mediated	
CAR	Phenobarbital Toxaphene

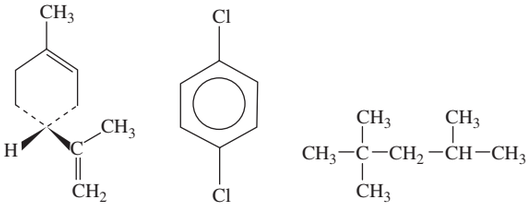
Cytotoxicity Cytotoxicity and consequent regenerative hyperplasia is well-documented mode of action for a variety of non–DNA-reactive chemical carcinogens (Dietrich and Swenberg, 1991). Chloroform-induced liver and kidney tumors and melamine-induced bladder tumors are classic examples of chemical carcinogens that are classified as functioning via a cytolethal mode of action (Bull et al., 1986; Butterworth, 1990; Larson et al., 1994; Pereira, 1994; Andersen et al., 1998). Chemicals that function through this mechanism produce sustained cell death, often related to metabolism of the chemical, that is accompanied by persistent regenerative growth, resulting in the potential for the acquisition of "spontaneous" DNA mutations and allowing mutated cells to accumulate and proliferate. This process then gives rise to preneoplastic focal lesions that upon further expansion can lead to tumor formation. Chloroform has been shown to induce mouse liver tumors only at doses of compound that produce liver necrosis, thus demonstrating an association between necrosis with compensatory hyperplasia and the resulting tumorigenicity, and also supports that a threshold for the induction of tumors is likely at doses that do not produce toxicity (Beddowes et al., 2003). It is important to note that the induction of cytotoxicity may be observed with many carcinogens both genotoxic and non-genotoxic when high toxic exposures occur. Thus, the induction of cytotoxicity with compensatory hyperplasia may contribute to the observed tumorigenicity of many carcinogenic chemicals at high-dose levels.

α2u-Globulin-Binding Drugs The carcinogens D-limonene, 1,4-dichlorobenzene, and trimethylpentane (Fig. 8-15) as well



D-Limonene 1,4-Dichlorobenzene 2,2,4-Trimethylpentane C_8H_{18}

Figure 8-15. *Examples of selective α2u-globulin-binding chemicals.*

unleaded gasoline induce renal tumors selectively in the male rat, and provide excellent examples of the species, sex, and tissue specificity of non–DNA-reactive carcinogens. The mechanism for the species and sex specificity is related to the ability of these compounds to bind to α2u-globulin, a protein synthesized by the male rat liver at the onset of puberty, as the mechanism of tumorigenesis. α2u-Globulin is filtered through the glomerulus, and only partially excreted (~50%) in the urine. The reabsorbed fraction accumulates in lysosomes of the P2 segment of the proximal tubules, where it is hydrolyzed to amino acids (Melnick et al., 1996). Chemicals with the ability to bind to α2u-globulin decrease the rate of digestion of α2u-globulin and result in the accumulation in the lysosomes, dysfunction of this organelle, and subsequent release of digestive enzymes and cell necrosis. The greater loss of tubule cells leads to increased cell proliferation in the P2 segment, which may be responsible for the tumor development and malignant transformation (Dietrich and Swenberg, 1991) (See Chap. 14 for additional details).

Receptor-Mediated

CAR Receptor-Mediated (Phenobarbital-Like Carcinogens)

Phenobarbital is a commonly studied non–DNA-reactive compound that is known to cause tumors by a non-genotoxic mechanism involving liver hyperplasia (Williams and Whysner, 1996). One feature seen following phenobarbital exposure is the induction of P450 enzymes, particularly Cyp2b (Nims and Lubet, 1996). Chemicals that functioned as P450 inducers in a manner similar to phenobarbital were classified as phenobarbital-like or P450-inducing carcinogens. Because a number of diverse chemicals are known to induce various members of the P450 system (e.g., dieldrin, ethanol, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin [TCDD]), the specificity of this effect to the carcinogenesis has been questioned. Recent evidence has shown that the induction of Cyp2b is mediated by activation of the constitutive androstane receptor (CAR), a member of the nuclear receptor family (Honkakoski et al., 1998; Ueda et al., 2002; Kodama et al., 2004). CAR-null mice show no induction of Cyp2b following phenobarbital exposure (Wei et al., 2000; Wang et al., 2015, 2017). Other phenobarbital responses that are critical for tumor formation include increased cell proliferation, inhibition of apoptosis, inhibition of gap junctional communication, hypertrophy, and development of preneoplastic focal lesions in the liver (Whysner et al., 1996; Elcombe et al., 2014), effects that have all been shown to be CAR-dependent (Wei et al., 2000; Kodama et al., 2004; Elcombe et al., 2014). CAR can be activated by both direct ligand binding and ligand-independent (indirect) mechanisms. Phenobarbital activates CAR indirectly by inhibiting epidermal growth factor receptor (EGFR) signaling (Mutoh et al., 2013). Phenobarbital binds to EGFR that inhibits the binding of EGF and prevents the activation of EGFR; disruption of EGFR signaling leading to dephosphorylation of receptor for activated C kinase 1, which further recruits PP2A (protein phosphatase 2A) and dephosphorylates CAR, releasing CAR into nucleus, where CAR forms a dimer with RXR and binds to PBREMs, resulting in increased gene expression (Fig. 8-16) (see Chapter 6 for additional details on CAR induction of CYP).

Peroxisome Proliferator–Activated Receptor α

A wide array of chemicals are capable of increasing the number and volume of peroxisomes in the cytoplasm of cells. These chemicals, termed peroxisome proliferators, include lipid-lowering fibrate drugs (e.g., ciprofibrate, clofibrate), herbicides (e.g., 2,4-dichlorophenoxyacetic acid), chlorinated solvents (e.g., trichloroethylene and perchloroethylene), perfluorinated compounds (e.g., perfluorooctane sulfonate and perfluorooctanoic acid), plasticizers (e.g., diethylhexylphthalate and other phthalates), and natural products. In addition, many of the chemicals within this group produce liver enlargement and hepatocellular carcinoma in rats and mice through non–DNA-reactive mechanisms (Lake, 1995; Reddy and Rao, 1997). Two additional tumor types are also associated with exposure to peroxisome-proliferating compounds: Leydig cell tumors and pancreatic acinar cell tumors in rats (Kennedy et al., 2004). Studies conducted either in vivo or in vitro in primary hepatocyte cultures have shown important interspecies differences in the hepatic peroxisome proliferation responses to chemicals. The rat and the mouse were clearly revealed as responsive species, whereas primates and the guinea pig proved to be nonresponders. The Syrian hamster exhibits an intermediate response (Bentley et al., 1993; Lake, 1995). The mechanism(s) involved in peroxisome proliferation and tumorigenesis went unrecognized for years. The currently accepted mode of action for this class of chemicals involves the agonist binding and/or activating the nuclear receptor, the PPARα. Largely through the use of PPARα knockout mice, it has been demonstrated that the activation of PPARα by agonists is needed for these chemicals to induce peroxisome proliferation and tumorigenesis in rodents (Issemann and Green, 1990; Lee et al., 1995; Peters et al., 1998, reviewed in Klaunig et al., 2003 and Corton et al., 2014). PPARα is highly expressed in cells that have active fatty acid oxidation capacity (e.g., hepatocytes, cardiomyocytes, enterocytes). It is well documented that PPARα plays a central role in lipid metabolism and acts as a transcription factor to modulate gene expression following ligand activation. This latter effect arises through the heterodimerization of PPARα and RXRα, which results in binding to response elements (PPREs) and subsequent modulation of target gene transcription (Fig. 8-17) (see Chap. 6). Following this event is the induction of cell proliferation and suppression of apoptosis (Marsman et al., 1992; James and Roberts, 1996; Burkhardt et al., 2001). Both of these events would be expected to affect tumor development as these effects would enhance the rate of fixation of DNA damage in the genome, leading to changes in gene expression, such as the silencing of tumor-suppressor genes or increased expression of oncogenes, or suppress apoptosis that may normally remove DNA-damaged, potentially tumorigenic, cells. Because humans are exposed to a number of these chemicals, the relevance of this mode of action to humans has been evaluated (Klaunig et al., 2003; Corton et al., 2014). Although the same events would be expected to occur in exposed humans, several species differences have been noted including a lack of induction of cell proliferation in nonhuman primates (Pugh et al., 2000), and the finding that PPARα in human liver is less than 10 percent that observed in rat or mouse liver (Palmer et al., 1998; Tugwood et al., 1998). Based on these kinetic and dynamic differences between species, it has been

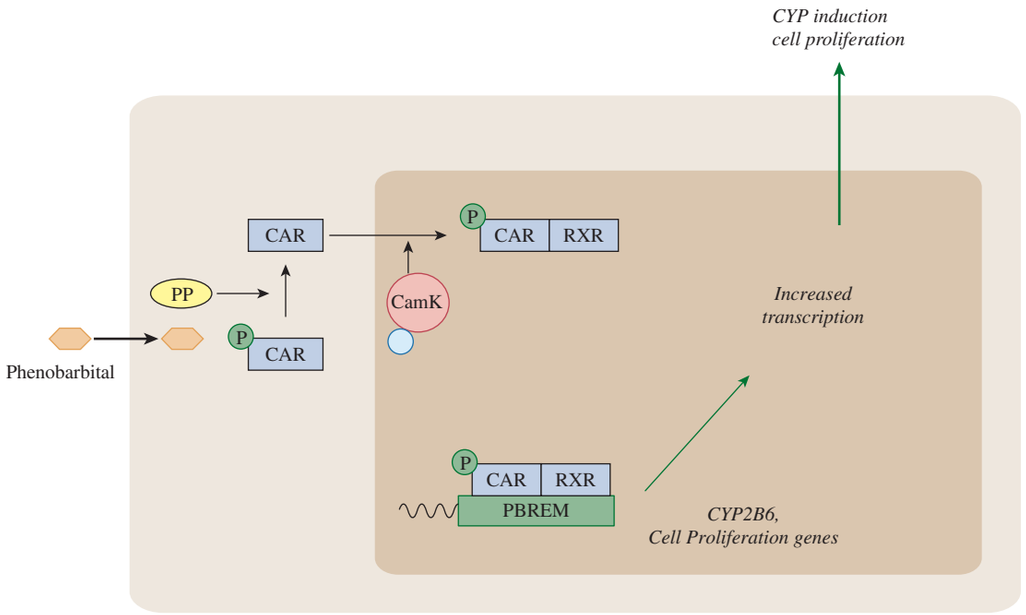


Figure 8-16. *Proposed mechanism for the involvement of the constitutive androstane receptor (CAR) in phenobarbital-induced gene expression changes.* EGFR, epithelial growth factor receptor; PP2A, protein phosphatase 2A; RXR, retinoic acid receptor; PBREM, phenobarbital response element. Phenobarbital activates CAR indirectly by inhibiting EGFR. Following dephosphorylation of CAR by protein phosphatase 2A, CAR translocates to nucleus and forms a dimer with RXR and binds to PBREMs, resulting in increased gene expression.

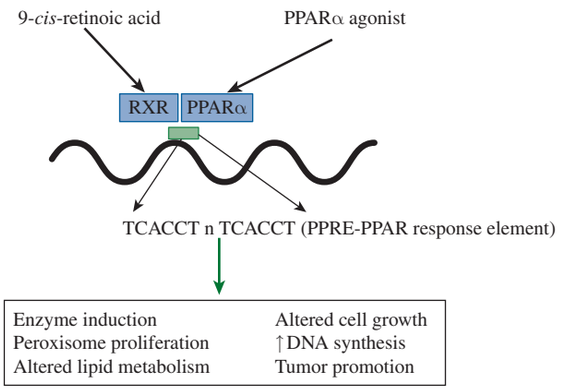

Figure 8-17. *Mechanism for altered gene expression by peroxisome proliferator activated receptor α (PPARα) agonist binding.* Following agonist binding to PPARα, the receptor dimerizes with the retinoic acid receptor (RXR). This complex then binds to PPREs, resulting in enhanced gene transcription.

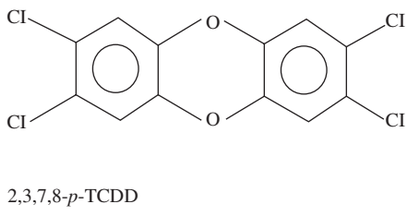

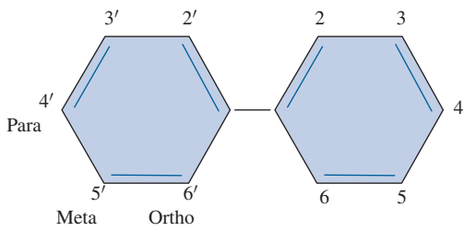

Figure 8-18. *Selective examples of aryl hydrocarbon receptor-binding chemicals.* Prototypical structure for PCBs or PBBs. PCBs and PBBs exhibit varying degrees of chlorination or bromination at positions 2-6 and 2′-6′ of the biphenyl molecule.

concluded that tumors are not likely to occur in humans by PPARα agonists (Klaunig et al., 2003; Corton et al., 2014).

Aryl Hydrocarbon Receptor Activators of the AhR including TCDD and selected polychlorinated- and brominated-biphenyl (PCBs and PBBs) compounds (Fig. 8-18) have been linked to tumor promotion in rodent livers (Pitot et al., 1982; IARC, 1997a, 1997b, 2010). The tumor response has been determined to be AhR-dependent (Knutson and Poland, 1982; Budinsky et al., 2014) (Fig. 8-19). Upon ligand binding to the AhR, the ligand bound AhR translocates to the nucleus, dimerizes with the Ah receptor nuclear translocator (ARNT), and binds to aryl hydrocarbon response elements (AREs also known as dioxin response elements [DRE] and xenobiotic response elements [XRE]) (for review see Nebert et al., 2000) (see Chap. 6). AhR-ARNT–dependent genes include cytochrome P450 family members, NAD(P)H:quinone oxidoreductase, a cytosolic aldehyde dehydrogenase 3, a UDP-glucuronosyltransferase, and a glutathione transferase (Nebert et al., 2000), genes that are involved in metabolic activation as well as detoxification of chemicals. It has been hypothesized that there are additional AhR-ARNT–dependent genes (Nebert et al., 2000). AhR knockout mice have a diminished response to tumor induction by AhR ligand, dibenzo(a,l)pyrene (Nakatsuru et al., 2004), and conversely, constitutively overexpressed AhR resulted in an

increased incidence of liver tumors (Moennikes et al., 2004), supporting the theory that agonist binding to AhR is a required event for tumor induction by this class of chemicals. As seen with other hepatic tumor-promoting chemicals, TCDD also inhibits apoptosis in hepatic foci (Stinchcombe et al., 1995).

Hormonal Mode of Action Hormonally active chemicals include steroids and peptide hormones that produce tissue-specific changes through interaction with a receptor. A number of non–DNA-reactive chemicals induce neoplasia through receptor-mediated mechanisms, and/or perturbation of hormonal balance. Trophic hormones are known to induce cell proliferation at their target organs. This action may lead to the development of tumors when the mechanisms of hormonal control are disrupted and some or other hormone shows persistently increased levels. Several well-studied examples include the induction of ovarian neoplasms via decreased estradiol and increased luteinizing hormone (LH) levels (Capen et al., 1995), and the induction of thyroid tumors in rats by phenobarbital-type P450 inducers (which modulate T3 and T4) (McClain, 1995; Whysner et al., 1996).

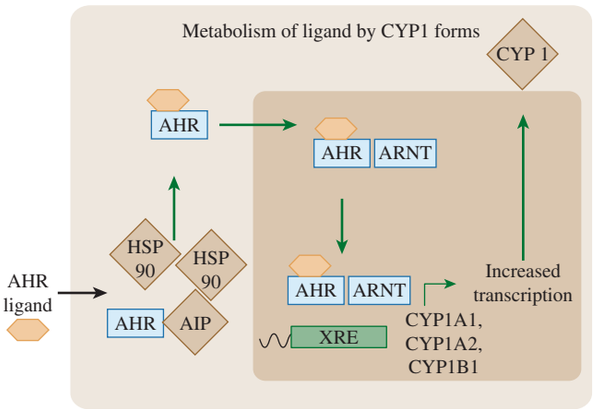

Figure 8-19. *Proposed mechanism of aryl hydrocarbon receptor (AhR) mediated gene expression.* ARNT, AhR nuclear transporter; XRE, xenobiotic response element. Non-ligand bound AhR is maintained in the cytoplasm via association with chaperone proteins (e.g., AIP, Hsp90). Following ligand binding, chaperone proteins dissociate and AhR translocates to the nucleus where it binds with ARNT. The heterodimer binds to XREs resulting in an increase in gene transcription.

Estrogenic Agents Estrogen and estrogen-mimic chemicals can induce tumors in estrogen-dependent tissue. Selective estrogenic chemicals (agonists and antagonists) are shown in Fig. 8-20. Oral administration of 17β-estradiol to female mice increases the incidence of mammary tumors (Welsch et al., 1977; Highman et al., 1978) whereas subcutaneous administration of estradiol to young female mice produced tumors of the cervix and vagina (Pan and Gardner, 1948). Evidence that estrogenic chemicals are carcinogenic to humans comes from epidemiological data on breast and ovarian cancer, which indicates that individuals with higher circulating estrogen levels and those with exposure to the potent estrogenic chemical diethylstilbestrol (DES) are at increased risk for cancer development. DES was first shown to induce mammary tumors in male mice following subcutaneous administration of the hormone. DES has been causally associated to the higher incidence of adenocarcinomas of the vagina and cervix in daughters of women treated with the hormone during pregnancy (Herbst and Scully, 1970; Herbst et al., 1972; Noller et al., 1972). The mechanism of action for DES is believed to function through its ability to induce aneuploidy (Li et al., 1997; Tsutsui et al., 1997). The effects of steroidal chemicals on the cell cycle (Sutherland et al., 1995) and on microtubule assembly (Metzler et al., 1996) may be important in the aneuploidy (aneuploidy is the presence of an abnormal number of chromosomes in a cell) inducing effects of some hormonal chemicals (Li et al., 1996).

Chronic exogenous administration of hormonally active chemicals including synthetic estrogens and anabolic steroids can

increase hepatic adenoma incidence in rats (Li et al., 1992) and in humans (IARC, 1997a, 1997b, 2007, 2012). Women of childbearing age showed sensitivity to hepatic adenoma formation, which was exacerbated by the use of oral contraceptives containing high concentrations of estrogenic compounds. These adenomas regress upon hormone cessation (Edmondson et al., 1977) and can progress with continued administration (Christopherson et al., 1978). Chronic administration (>8 years) is required to detect this increased liver tumor risk from oral contraceptives (Tavani et al., 1993). It is important to note that the liver tumor effects seen with the early introduced oral contraceptives were related to the high dose of estrogen compounds in the formulation.

Estrogenic substances in plants (phytoestrogens) have been identified. These include genistein, daidzein, glycitein, equol, and their metabolites found in soy products and various lignan derivatives. In addition, a number of environmental nonsteroidal synthetic compounds demonstrate apparent estrogenic activity (e.g., nonylphenol, bisphenol-A, chlorinated hydrocarbons; Soto et al., 1997). The potential for these chemicals to induce cancer in humans remains a highly debated topic.

Species and tissue specificity in response to receptor-mediated carcinogenesis is often observed. As an example, tamoxifen is antiestrogenic in the chick oviduct, estrogenic in the mouse uterus with acute administration, but antiestrogenic with chronic administration in the same tissue, whereas it is estrogenic in the rat uterus. In contrast estrogens have also been shown to act as a protective chemical in prostate cancer. Although the differences observed may be in part due to tissue and species differences in coactivator and corepressor levels and availability, other pharmacokinetic and pharmacodynamic properties are likely to participate in the response (Carthew et al., 1995). To further exemplify the complexity of the role of estrogen in cancer development, estrogens have also been reported to function in a protective manner in androgen-dependent prostate cancer (Bosland, 2005).

Induction of ovarian tumors in mice by dietary administration of nitrofurantoin, an antibiotic used to treat urinary tract infections is an example of a tumorigenic effect secondary to drug-induced hormonal disturbance. Nitrofurantoin treatment resulted in ovarian atrophy with absence of Graafian follicles and sterility. The reduction of follicles induced a reduction of sex steroid hormones by the ovary, resulting in increased production of gonadotrophins, notably LH. This was due to the decreased negative feedback on the hypothalamus–pituitary axis by estrogens. Persistent stimulation by LH of the murine ovary cells resulted in development of tumors (Capen et al., 1995). A similar tumorigenic effect on the ovary occurs with dopamine agonists. The induction of hypoprolactinemia changes the number of LH receptors and leads to enhanced sensitivity to LH and a higher stimulation by LH similar to nitrofurantoin.

Thyroid Hormone A reduction of thyroid hormone concentrations (T4 and/or T3) and increased thyroid-stimulating hormone (TSH) have been shown to induce neoplasia in the rodent thyroid. TSH increases proliferative activity in the thyroid. After chronic treatment chemical-induced increase in TSH leads to follicular cell hypertrophy, hyperplasia, and eventually neoplasia. Inducers of metabolic enzymes in the rat liver, for example with phenobarbital (Hood et al., 1999), results in increased thyroid hormone metabolism and leads to an increase in TSH levels (Fig. 8-21). It is this latter event that is associated with the development of thyroid tumors in rodents. Recent evidence suggests that the enhancement of metabolism and excretion of thyroid hormones by xenobiotics (via induction of phase II enzymes in particular UDP-glucuronosyltransferase) is a consequence of CAR, PXR, AhR, and/or PPARα activation (Shelby and Klaassen, 2006; Yanagiba et al., 2009). Qualitatively, thyroid gland function in rodents is much more susceptible to disturbances of thyroid hormone levels than in humans. In contrast to humans, rodents lack the thyroid-binding globulin, which is the predominant plasma protein (at least in humans) responsible for thyroxin binding and transport (McClain, 1995). A relatively higher level of functional activity is present in rat thyroid compared to humans.

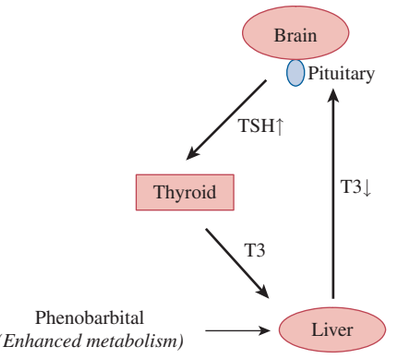

Figure 8-21. *Mechanism for phenobarbital-induced thyroid tumors.* Through alteration of gene expression, phenobarbital enhances metabolism of thyroid hormone (T3) resulting in enhanced TSH production. Increased TSH then leads to increased cell proliferation in the thyroid.

DNA Methylation and Carcinogenesis Post-DNA synthetic methylation of the five position on cytosine (5-methylcytosine; 5mC) is a naturally occurring modification to DNA in higher eukaryotes that influences gene expression (Holliday, 1990) (Fig. 8-22). Methylation of DNA occurs through an enzymatic reaction catalyzed by DNA methyltransferases (DNMTs). Under normal conditions, DNA is methylated symmetrically on both strands. Immediately following DNA replication, the newly synthesized double-stranded DNA contains hemimethylated sites that signal for DNA maintenance methylases to transfer methyl groups from *S*-adenosylmethionine to cytosine residues on the new DNA strand (Hergersberg, 1991). The degree of methylation within a gene inversely correlates with the expression of that gene; hypermethylation of genes is associated with gene silencing, whereas hypomethylation results in an enhanced expression of genes. Several chemical carcinogens are known to modify DNA methylation, methyltransferase activity, and chromosomal structure. During carcinogenesis, both hypomethylation and hypermethylation of the genome have been observed (Counts and Goodman, 1995; Robertson and Jones, 2000; Luczak and Jagodzinski, 2006). Alterations in methylation of promoter regions may mimic the effect of mutations of various tumor suppressor genes or proto-oncogenes, resulting in carcinogenesis. Increased methylation of CpG islands have been observed in bladder cancer and tumor-suppressor genes such as the retinoblastoma gene, $p16^{ink4a}$, and $p14^{ARF}$ have been reported to be hypermethylated in tumors (Stirzaker et al., 1997; Belinsky et al., 1998; Myöhänen et al., 1998; Salem et al., 2000; Esteller et al., 2001). Hypomethylation has been associated with increased mutation rates. Most metastatic neoplasms in humans have significantly lower 5MeC than normal tissue (Gama-Sosa et al., 1983); furthermore, many oncogenes are hypomethylated and their expression amplified.

Choline and methionine, from dietary sources, are a common source of methyl groups used in methylation reactions. Rats exposed to choline and/or methionine-deficient diets displayed hepatocellular proliferation and neoplasia (Abanobi et al., 1982; Wainfan and Poirier, 1992) (Table 8-12). In rodents fed choline or

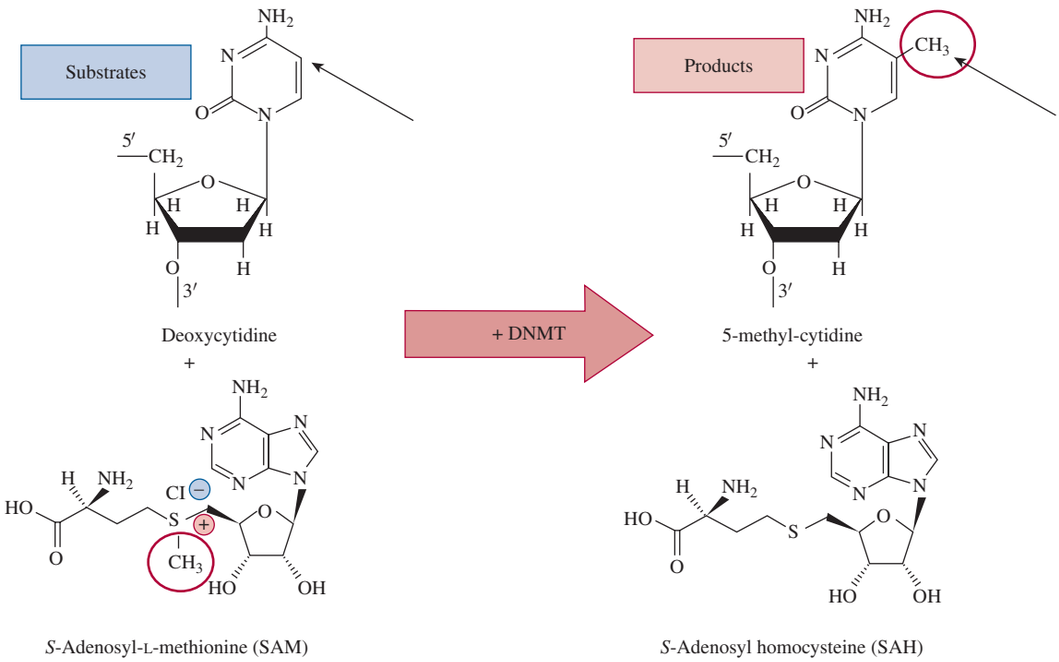

Figure 8-22. *Substrates and products involved in DNA methylation.* Methylation of DNA occurs through an enzymatic reaction catalyzed by DNA methyltransferases (DNMTs). DNA is methylated at the five-position of cytosine and requires the cofactor *S*-adenosylmethionine.

Table 8-12

Evidence for Choline Depletion in Hepatocarcinogenesis

CHOLINE	METHIONINE	FOLATE	HEPATOCELLULAR CARCINOMA (%)	DURATION (MONTHS)	REFERENCES
–	+	+	100	12	Nakae et al. (1992)
–	+	+	73	12	Chandar and Lombardi (1988)
–	Low	–	100	15	Henning et al. (1997)
–	–	+	51	13	Ghoshal and Farber (1984)

the hepatic neoplasia is thought to arise from hypomethylation of *c-myc*, *c-fos*, and *c-H-ras* proto-oncogenes, due to the decreased availability of *S*-adenosylmethionine (Newberne et al., 1982; Wainfan and Poirier, 1992). Chemicals such as diethanolamine result in hepatic neoplasia, in part, via a mechanism involving choline depletion, altered methylation, and modulation of gene expression (Kamendulis and Klaunig, 2005; Bachman et al., 2006). Reactive oxygen species have also been shown to modify DNA methylation resulting in changes in DNA methylation profiles through interfering with the ability of methyltransferases to interact with DNA, leading to hypomethylation of CpG sites (Weitzman et al., 1994; Turk et al., 1995). Also, the presence of 8-OHdG in DNA can lead to hypomethylation of DNA because this adduct, if present in CpCpGpGp sequences, will inhibit the methylation of adjacent C residues. Thus, oxidative DNA damage may be an important contributor to the carcinogenesis process brought about by the loss of DNA methylation, allowing the expression of normally quiescent genes. Also, the abnormal methylation pattern observed in cells transformed by chemical oxidants may contribute to an overall aberrant gene expression and promote the tumor process.

Methylation of deoxycytidine residues is a well-studied DNA adduct. This reaction occurs by the transfer of a methyl group from *S*-adenosylmethionine by DNA methyltransferases (Holliday, 1990). Methylation of DNA results in heritable expression or repression of genes, with hypomethylation associated with active transcription of genes, whereas hypermethylated genes tend to be rarely transcribed (Pogribny and Beland, 2013). Chemical carcinogens may inhibit DNA methylation by several mechanisms including forming covalent adducts, single-strand breaks in the DNA, alteration of methionine pools, and inactivation of the DNA methyltransferase responsible for methylation (Riggs and Jones, 1983). The importance of DNA methylation in chemical carcinogenesis is discussed further later in this chapter.

MicroRNA and Chemical Carcinogenesis MicroRNAs (miRNAs) are small noncoding RNAs, usually consist of 21 to 25 nucleotides, that typically regulate gene expression through repression or degradation of targeted messenger RNAs (mRNAs), controlling genes involved in multiple cellular processes. Dysregulation of mRNAs has been implicated in the development (initiation), promotion, and progression of cancer (Lee and Dutta, 2009;

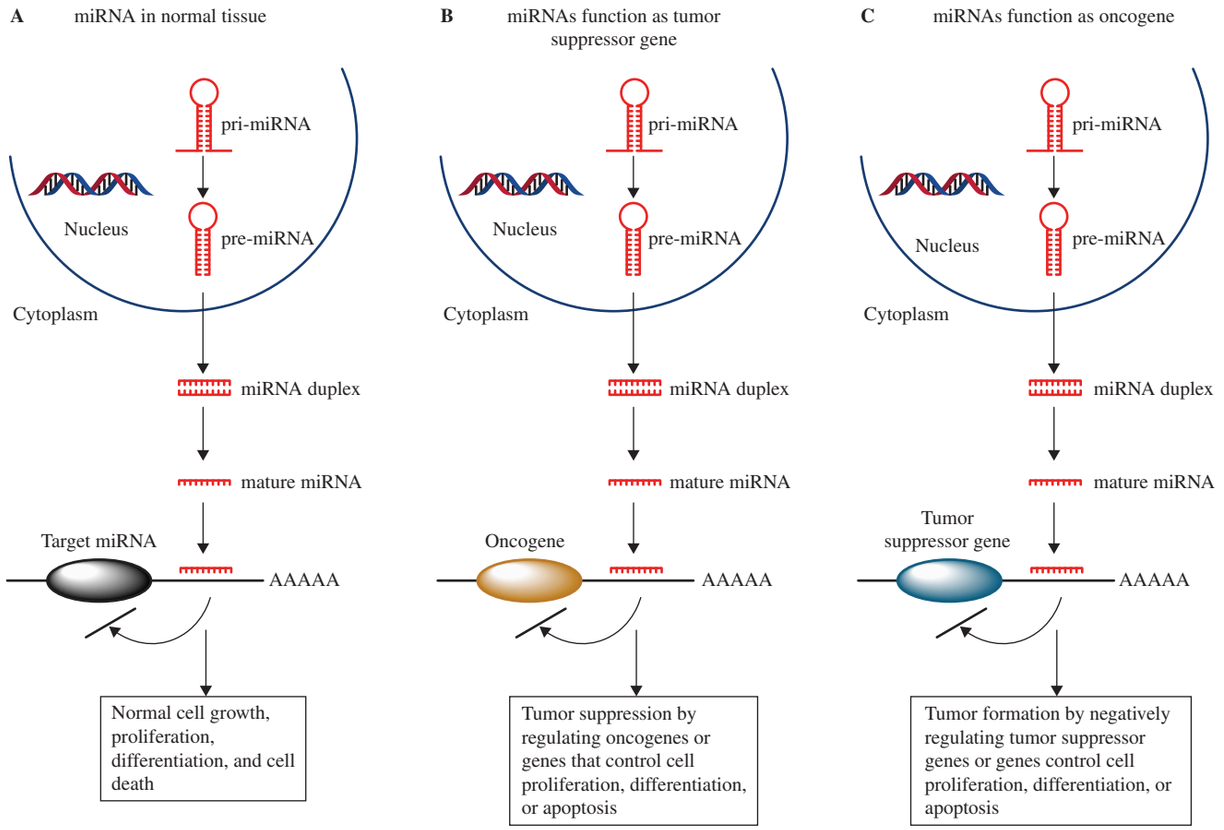

Figure 8-23. *Role of microRNA in carcinogenesis.*

Chen, 2010). Emerging evidence has demonstrated the involvement of miRNA deregulation in the early stages of lung, liver, and breast carcinogenesis induced by chemical carcinogens, suggesting their major role as contributors to the pathogenesis of cancer (Pogribny, 2009; Pogribny et al., 2016). Many miRNAs function as antitumor agents (or tumor suppressor genes), others behave as oncogenes, commonly known as oncomiRNAs (Esquela-Kerscher and Slack, 2006) (Fig. 8-23). Some well-defined oncomiRNA are miR-17, miR-19, miR-21, and miR-155, whose upregulation have been linked to environmental carcinogens exposure (Izzotti and Pulliero, 2014). Thus, the carcinogenic effect of a carcinogen can be dependent on the balance between these two groups of miRNAs. The alterations in miRNAs expression following exposure to carcinogens are usually tissue and chemical specific. Phenobarbital and bis(2-ethylhexyl) phthalate treatment of rats for 90 days produced a persistent, progressive, and highly correlated induction of the miR-200a/200b/429 and miR-96/182 clusters in liver tissue (Koufaris et al., 2012, 2013). The miRNA profiles and miRNAs specific to carcinogen exposure also have the potential to be used as indicators of the carcinogenic process, biomarkers for carcinogen exposure, and for the identification of potential chemical carcinogens.

Immunosuppression and Carcinogenesis Cancer immune surveillance is considered to be an essential host protection mechanism to inhibit carcinogenesis by identifying and removing early preneoplastic cells from the body and to maintain cellular homeostasis (Swann and Smyth, 2007; Vesely et al., 2011; Corthay, 2014). An association between the development of cancer and immunosuppression has long been recognized (Penn and Starzl, 1972). The initial evidence for the role of immunosuppression in cancer induction resulted from the observation that transplant patients receiving immunosuppression therapy developed tumors (Penn et al., 1969, 1971; Penn and Starzl, 1970). Solid-organ transplant recipients are at a three- to fivefold increased risk of developing de novo cancers compared with the general population (Billups et al., 2015). Evading immune recognition and destruction is one of the hallmarks of cancer identified by Hanahan and Weinberg (2011). Immune suppression has also been proposed as a possible mode of action of non-genotoxic carcinogens (USEPA, 2005; Hattis et al., 2009).

It has long been appreciated that inflammation secondary to chronic infection or irritation is a predisposal to cancer induction (Colotta et al., 2009; Hanahan and Weinberg, 2011). Prolonged inflammation can destroy immune cells leading to immune suppression. This mechanism of immunosuppression has been suggested to be involved in the carcinogenesis of environmental immune disruptors such as bisphenol A, atrazine, phthalates, and PBDEs (Thompson et al., 2015).

Oxidative Stress and Chemical Carcinogenesis Experimental evidence has shown that increases in reactive oxygen in the cell, through either physiological modification or chemical carcinogen exposure, contribute to the carcinogenesis processes (Vuillaume, 1987; Trush and Kensler, 1991; Witz, 1991; Guyton and Kensler, 1993). Reactive oxygen species encompass a series of reactive compounds including the superoxide anion ($^{\bullet}O_2^-$), hydroperoxyl radical ($HO_2^{\bullet}$), hydrogen peroxide (H_2O_2), and the hydroxyl radical ($^{\bullet}OH$), all derived through the reduction of molecular oxygen

Table 8-13

Pathways for Intercellular Oxidant Generation

Generation of reactive oxygen species via reduction of molecular oxygen

$O_2 + e^- \rightarrow O_2^{\cdot-}$ (superoxide anion)

$O_2^{\cdot-} + H_2O \rightarrow HO_2^{\cdot}$ (hydroperoxyl radical)

$HO_2^{\cdot} + e^- + H \rightarrow H_2O_2$ (hydrogen peroxide)

$H_2O_2 + e^- \rightarrow OH^- + {}^{\cdot}OH$ (hydroxyl radical)

A series of oxygen radicals are produced by the reduction of molecular oxygen. Of the radicals produced, the hydroxyl radical, hydroperoxyl radical, and the superoxide anion are sufficiently reactive and may interact with biomolecules.

Thioredoxin	

Oxidants > Antioxidants → Oxidative Damage (DNA, RNA, Lipid, Protein)

Oxidants can be produced via both endogenous and exogenous sources. Antioxidants function to maintain the cellular redox balancing. However, excess production of oxidants and/or inadequate supplies of antioxidants result in damage to cellular biomolecules and may impact on neoplastic development.

(Table 8-13) (see Chap. 3). Oxygen radicals can be produced from both endogenous and exogenous sources and are typically counterbalanced by antioxidants (Table 8-14). Antioxidant defenses are both enzymatic (e.g., superoxide dismutase, glutathione peroxidase, and catalase) and nonenzymatic (e.g., vitamin E, vitamin C, β-carotene, and glutathione) (Betteridge, 2000; Abuja and Albertini, 2001); importantly, many of these antioxidants are provided through dietary intake (Clarkson and Thompson, 2000).

Endogenous sources of reactive oxygen species include oxidative phosphorylation, P450 metabolism, peroxisomes, and inflammatory cell activation (Table 8-14). Within the mitochondria, a small percentage of oxygen is converted into the superoxide anion via 1-electron reduction of molecular oxygen. Superoxide can be dismutated by superoxide dismutase to yield hydrogen peroxide (Barber and Harris, 1994). In the presence of partially reduced metal ions, hydrogen peroxide is converted into the highly reactive hydroxyl radical through Fenton and Haber–Weiss reactions (Betteridge, 2000). Neutrophils, eosinophils, and macrophages are another intracellular source of reactive oxygen species. Activated macrophages, through a "respiratory burst," elicit a rapid increase in oxygen uptake that gives rise to a variety of reactive oxygen species including superoxide anion, hydrogen peroxide, and nitric oxide. The release of cytokines and reactive oxygen intermediates from activated Kupffer cells (the resident macrophage of the liver) has been implicated in hepatotoxicological and hepato-carcinogenic events (Rose et al., 1999; Rusyn et al., 1999). Recent studies show that activation of the Kupffer cell may function at the promotion stage of carcinogenesis. Reactive oxygen species can also be produced by cytochrome P450-mediated mechanisms including (1) redox cycling in the presence of molecular oxygen, (2) peroxidase-catalyzed single electron drug oxidations, and (3) "futile cycling" of cytochromes P450 (Parke, 1994; Parke and Sapota, 1996). Ethanol, phenobarbital, and a number of chlorinated and nonchlorinated compounds such as dieldrin, TCDD, and lindane are among the xenobiotics shown to increase reactive oxygen species through P450-mediated mechanisms (Eksrom and Ingleman-Sundberg, 1989; Rice et al., 1994; Klaunig et al., 1997). PPARα activators (e.g., clofibrate, phthalate esters) induce cytochrome P450 (CYP4A) and increase the formation of peroxisomes. As such, an increase in H_2O_2 production often accompanies exposure to chemicals that stimulate the number and activity of peroxisomes (Rao and Reddy, 1991; Wade et al., 1992). A number of agents that induce cancer also induce reactive oxygen species formation, oxidative stress, and frequently oxidative damage to the cell (Rice-Evans and Burdon, 1993; Klaunig et al., 1997, 2011).

Oxidative DNA Damage and Carcinogenesis Reactive oxygen species left unbalanced by antioxidants can result in damage to cellular macromolecules. Reactive oxygen species can produce single- or double-stranded DNA breaks, purine, pyrimidine, or deoxyribose modifications, and DNA cross-links (von Sonntag, 1987; Dizdaroglu, 1992; Demple and Harrison, 1994). Persistent DNA damage can result in either arrest or induction of transcription, induction of signal transduction pathways, replication errors, and genomic instability, events that are potentially involved in carcinogenesis. Oxidation of guanine at the C8 position results in the formation of 8-hydroxydeoxyguanosine (8-OHdG; see Fig. 8-7). The 8-OHdG adduct is mutagenic in bacterial and mammalian cells, produces dose-related increases in cellular transformation, and causes G → T transversions that are commonly observed in mutated oncogenes and tumor-suppressor genes (Shibutani et al., 1991; Moriya, 1993; Hussain and Haris, 1998; Zhang et al., 2000). During DNA replication, 8-OHdG in the nucleotide pool can incorporate into the DNA template strand opposite dC or dA resulting in A:T to C:G transversions (Cheng et al., 1992; Demple and Harrison, 1994). Oxidative damage to mitochondrial DNA and mutations in mitochondrial DNA have been identified in a number of cancers (Schumacher et al., 1973; Horton et al.,

1996; Cavalli and Liang, 1998; Tamura et al., 1999; Chatterjee et al., 2006). Compared to nuclear DNA, the mitochondrial genome is relatively susceptible to oxidative base damage due to (1) close proximity to the electron transport system, a major source of reactive oxygen species (Barber and Harris, 1994); (2) mitochondrial DNA is not protected by histones; and (3) DNA repair capacity is limited in the mitochondria (Bohr and Dianov, 1999; Sawyer and Van Houten, 1999). Although many pathways exist that enable the formation of oxidative DNA damage, mammalian cells also possess specific repair pathways for the remediation of oxidative DNA damage (Tchou and Grollman, 1993; Fortini et al., 1999).

Aside from oxidized nucleic acids, oxygen radicals can also damage cellular biomembranes resulting in lipid peroxidation. Peroxidation of biomembranes generates a variety of products including reactive electrophiles, such as epoxides and aldehydes, and malondialdehyde (MDA) (Janero, 1990). MDA is a highly reactive aldehyde and exhibits reactivity toward nucleophiles, and can form MDA–MDA dimers. Both MDA and the MDA–MDA dimers are mutagenic in bacterial assays and the mouse lymphoma assay (Riggins and Marnett, 2001).

Oxidative Stress and Cell Growth Regulation Reactive oxygen species production and oxidative stress can affect both cell proliferation and apoptosis (Cerutti, 1985; Burdon, 1995; Slater et al., 1995). H_2O_2 and superoxide anion can induce cell proliferation in several mammalian cell types (D'Souza et al., 1993). Conversely, high concentrations of reactive oxygen species can initiate apoptosis (Dypbukt et al., 1994). Low levels of reactive oxygen species influence signal transduction pathways and alter gene expression (Fiorani et al., 1995). Many xenobiotics, by increasing cellular levels of oxidants, alter gene expression through activation of signaling pathways including cAMP-mediated cascades, calcium-calmodulin pathways, and transcription factors such as AP-1, Nrf2, Hif1, and NF-κB as well as signaling through mitogen-activated protein (MAP) kinases (extracellular signal-regulated kinases [ERK], c-Jun N-terminal kinases [JNK], and the p38 kinases) (Klaassen and Reisman, 2010; Kerr, 1992; Muller et al., 1997; Timblin et al., 1997; Klaunig et al., 2011). Activation of these signaling cascades by reactive oxygen species induced by chemical carcinogens ultimately leads to altered gene expression for a number of genes including those affecting proliferation, differentiation, and apoptosis (Hollander and Fornace, 1989; Amstad et al., 1992; Pinkus, 1993; Zawaski, 1993; Brown et al., 1998; Chang and Karin, 2001; Martindale and Holbrook, 2002) (Fig. 8-24). Activation of NF-κB, a ubiquitously expressed transcription factor, is regulated, in part, by reactive oxygen species and the cellular redox status. NF-κB activation has been observed following a variety of extracellular stimuli including exposure to chemical carcinogens and physical agents that induce oxidative stress (Beauerle et al., 1988; Li and Karin, 1998; Schulze-Oshoff et al., 1998; Pahl, 1999; Rusyn et al., 1999; Nebreda and Porrai, 2000; Glauert et al., 2001; Molina et al., 2001) (Fig. 8-25).

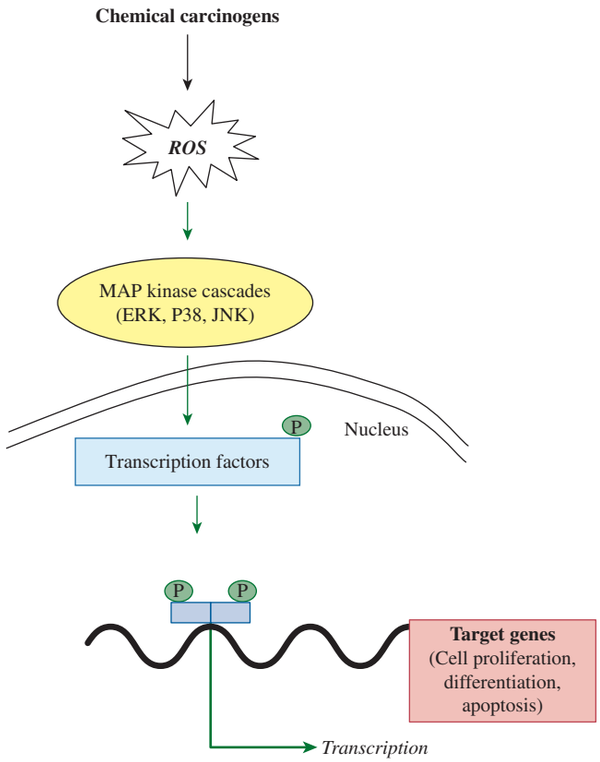

Figure 8-24. *Role of reactive oxygen species (ROS) on altered gene expression.* Many chemical carcinogens increase ROS and activate signaling cascades, such as the mitogen activated (MAP) kinase family. These serene/threonine kinases activate transcription factors, leading to DNA binding and gene expression changes.

Gap Junctional Intercellular Communication and Carcinogenesis

Cells within an organism communicate in a variety of ways including through gap junctions, which are aggregates of connexin proteins that form a conduit between two adjacent cells (Loewenstein, 1981) (Fig. 8-26). Gap junctional intercellular communication appears to play an important role in the regulation of cell growth and cell death, in part, through the ability to exchange small molecules (<1 kDa) between cells through gap junctions. Loss of gap junctions or decreased cell-to-cell communication is seen during liver regeneration following partial hepatectomy, a situation in which gap junction expression remains decreased until liver mass and lobular conformation are restored. Aberrant growth control is an essential feature of cancer cells, and because the absence or reduction in cell-to-cell communication has been observed between cancer cells, between cancer and normal cells, and in transformed cells, it has been speculated that altered gap junctional cell communication is involved in carcinogenesis (Trosko and Ruch, 1998). If cell communication is blocked between tumor and normal cells, the exchange of growth inhibitory signals from normal cells would be prevented from acting on initiated cells, thus allowing the potential for unregulated growth and clonal expansion of initiated cell populations. This would therefore allow for the acquisition of additional genetic changes that may lead to neoplastic transformation (Klaunig and Ruch, 1990).

Intercellular communication is also decreased by growth factor administration and following exposure to a variety of tumor-promoting compounds (e.g., phenobarbital, phthalates, dieldrin, phorbol esters). Tumor-promoting chemicals inhibit gap junctional intercellular communication in a number of cell types following exposure both in vivo and in vitro (Klaunig and Ruch, 1990; Klaunig et al., 1990a). The ability of a tumor-promoting compound to block cell-to-cell communication in cultured cells correlates with its ability to induce rodent tumors (Klaunig and Ruch, 1987). In addition, the inhibition of gap junctional intercellular communication by tumor promoters appears to be tissue- and species-specific; they produce inhibition in target organs and sensitive species, whereas they do

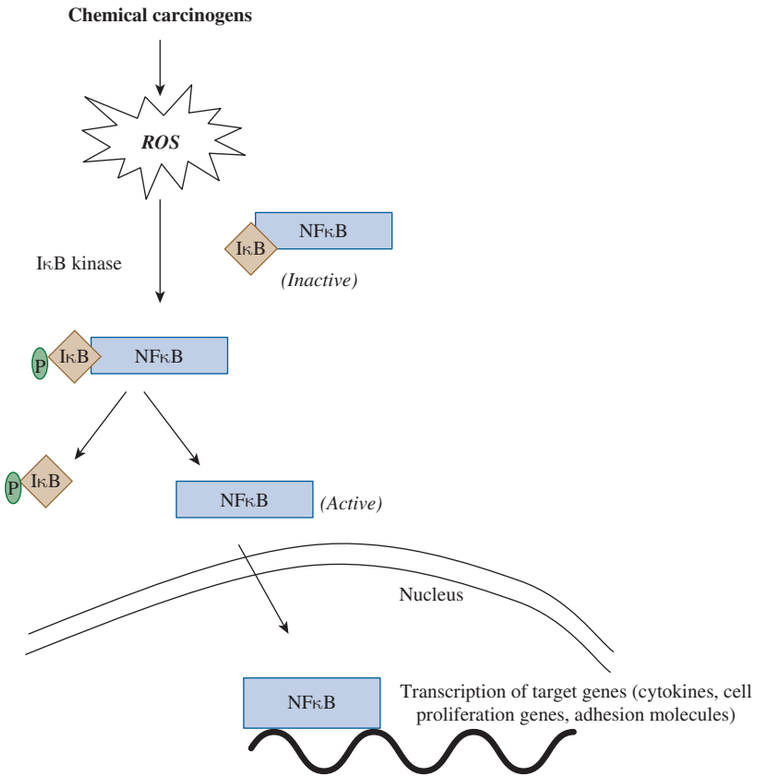

Figure 8-25. *Interaction between reactive oxygen species (ROS) and NFκB-induced gene expression.* A number of chemicals that increase ROS have been shown to activate NFκB. It is proposed that ROS enhance the dissociation of IκB from the NFκB/IκB complex leading to active NFκB. NFκB can then translocate into the nucleus where it binds DNA and increases gene transcription.

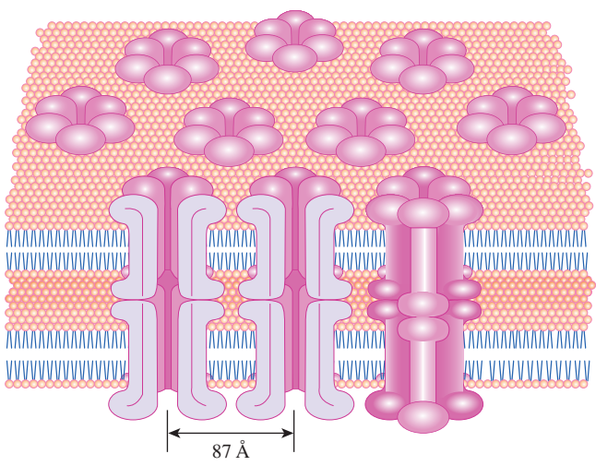

Figure 8-26. *Diagram of a gap junction traversing between two adjacent cells.* Connexons made up of six connexin proteins form the conduit between the two cells. (Reproduced with permission from Feldman RS, Quenzer LF. *Fundamentals of Neuropsychopharmacology*. Strauer Associates, Inc.; 1984.)

not inhibit cell-to-cell communication in nontarget tissues for carcinogenicity (Klaunig and Ruch, 1987). The mechanisms by which tumor promoters inhibit intercellular communication are not clear but may be due to decreased synthesis and/or enhanced degradation of gap junction proteins in the cell, reducing the number of channels in cell membranes, or other changes that modulate gap junction function and/or protein expression (Sugie et al., 1987; Klaunig and Ruch, 1990; Klaunig, 1991). Alternately, transient inhibition of gap junctional communication is under second messenger control (calcium and cAMP for example) (Klaunig and Ruch, 1990).

Inorganic Carcinogens

Metals Several metals exhibit carcinogenicity in experimental animals and/or exposed humans. Table 8-15 provides a listing of some common metals and their corresponding carcinogenicity in animals and humans. A recent IARC review has examined in detail inorganic compounds deemed human carcinogens (IARC, 2012). Additional details on selected compounds are provided below. As with all carcinogenic compounds, appreciation for the dose-response characteristics of the compound is important in understanding the relative risk to humans. (Chapter 23 provides additional information on toxicity and carcinogenicity of metals.)

Arsenic Arsenic is a naturally occurring metal. Arsenic is found in food, water, soil, and air. Arsenic is absorbed by plants and concentrated in the plant. Some seafood also contains arsenic. As such, human exposure to arsenic can occur from arsenic-containing water, soil, food, and air (on dust particles). Most exposure to inorganic arsenic occurs through arsenic-containing drinking water and to a lesser extent through food, while most organic arsenic exposure is through consuming seafood. Arsenic compounds are poorly mutagenic in both bacterial and mammalian cell assays (Lofroth and Ames, 1978). Metallic arsenic, arsenic trioxide, sodium arsenite, sodium arsenate, potassium arsenite,

Table 8-15

Carcinogenicity of Metals

	ANIMAL			HUMAN	
METAL	SPECIES	TUMOR SITE	TUMOR TYPE	EXPOSURE	TUMOR TYPE

lead arsenate, calcium arsenate, and pesticide mixtures containing arsenic have been tested for carcinogenicity in experimental animals (IARC, 1980, 1987, 2004, 2012). Based on the overall findings in animals, there is sufficient evidence in experimental animals for carcinogenicity of inorganic arsenic compounds. In addition, arsenic and inorganic arsenic compounds have been deemed to be carcinogenic to humans. Epidemiological studies of humans exposed to arsenic compounds demonstrated that exposure to inorganic arsenic compounds increases the risk of cancer in the skin, lung, digestive tract, liver, bladder, kidney, as well as lymphatic and hematopoietic systems (IARC, 1973, 1980, 2012; Martinez et al., 2011). Several epidemiological studies have reported dose–response relationships between arsenic in drinking water and several types of cancer, including bladder, kidney, lung, and skin (Cantor, 1997; Ferreccio et al., 2000). The mechanisms for cancer formation are unclear but are thought to possibly involve the induction of oxidative stress, altered cell signaling, modulation of apoptosis, and/or altered cell cycle (Harris and Shi, 2003; Quian et al., 2003; Hughes and Kitchin, 2006). The latency period in humans of arsenic-related carcinogenesis is considered to be 30 to 50 years. The first signs of chronic exposure, frequently seen in water supplies contaminated with arsenic, are skin pigmentation, depigmentation, hyperkeratosis of palms and soles, and skin lesions. A unique peripheral vascular disease associated with chronic arsenic exposure is black foot disease, starting with numbness and ulceration of extremities and ending in gangrene and spontaneous amputations (Chen et al., 1988). Dimethylarsinic acid and monomethylarsonic acid are possibly carcinogenic to humans. Arsenobetaine and other organic arsenic compounds are not well metabolized in humans and thus are not carcinogenic to humans (IARC, 1987, 2012).

Beryllium Most exposure of humans to beryllium occurs in the workplace, by inhalation of beryllium dust or fumes from the burning of coal or fuel oil and in tobacco smoke, by the ingestion of many fruits and vegetables and water, or through natural occurrence in soils. Mutagenicity tests for beryllium and its salts are either negative or weakly positive (Gordon and Bowser, 2003; IARC, 2012). Mechanistically, beryllium salts bind to nucleoproteins and inhibit enzymes involved in DNA synthesis, resulting in infidelity of DNA synthesis and also induce gene mutations in cultured cells (Leonard and Lauwerys, 1987). Studies in animal models have consistently reported increases in lung tumors in rodents and nonhuman primates exposed to beryllium or beryllium compounds (IARC, 1993; Finch et al., 1996; NTP, 1999). Beryllium metal and several beryllium compounds (e.g., beryllium-aluminum alloy, beryl ore, beryllium chloride, beryllium hydroxide, beryllium sulfate tetrahydrate, and beryllium oxide) induced lung tumors in rats. Beryllium oxide and beryllium sulfate produced lung cancer (anaplastic carcinoma) in monkeys after intrabronchial implantation or inhalation. In rabbits, osteosarcomas were reported after exposure to beryllium metal, beryllium carbonate, beryllium oxide, beryllium phosphate, beryllium silicate, or zinc beryllium silicate (IARC, 1993).

Beryllium and beryllium compounds have been classified as human carcinogens (Group 1) based on animal studies and evidence of carcinogenicity in humans (IARC, 1993, 2012; OSHA, 2017). Epidemiological studies indicate an increased risk of lung cancer in occupational groups exposed to beryllium or beryllium compounds (Steenland and Ward, 1991; Ward et al., 1992; Sanderson et al., 2001; Schubauer-Berigan et al., 2008). An association with lung cancer has consistently been observed in occupational populations exposed to beryllium or beryllium compounds. Acute beryllium pneumonitis, a marker for exposure to beryllium, has been shown to be associated with higher lung cancer rates (Steenland and Ward, 1991). In contrast, others have failed to observe a direct relationship between beryllium and human cancer risk (Boffetta et al., 2012, 2016).

Cadmium Cadmium exposure to humans is predominantly through consumption of food and drinking water, inhalation of cadmium-containing particles from ambient air or cigarette smoke, or ingestion of contaminated soil and dust. Animal studies have shown that cadmium and cadmium compounds induce tumor formation at various sites in multiple species of experimental animals, following multiple exposure routes, including the induction of prostate tumors in rats, testicular tumors in rats and mice, lymphoma in mice, adrenal gland tumors in hamsters and mice, and lung and liver tumors in mice (IARC, 1993; Waalkes et al., 1994, 1999). It has been suggested that ionic cadmium, or compounds that release ionic cadmium, results in genetic damage, and thus represents the carcinogenic species. Increased frequencies of chromosomal aberrations (changes in chromosome structure or number) have been observed in lymphocytes of workers occupationally exposed to cadmium. Many studies of cultured mammalian cells have shown that cadmium compounds cause genetic damage, including gene mutations, DNA strand breaks, chromosomal damage, cell transformation, and disrupted DNA repair (IARC, 1993).

Cadmium and cadmium compounds have been classified as known human carcinogens based on evidence of carcinogenicity in humans, including epidemiological and mechanistic information that indicate a causal relationship between exposure to cadmium and cadmium compounds and human cancer (9th RoC, 2000). Epidemiological studies of cadmium workers found that exposure to various cadmium compounds increased the incidence or risk of death from lung cancer (IARC, 1993, 2012). Follow-up analysis of some of these cohorts has confirmed that cadmium exposure is associated with elevated lung cancer risk under some industrial circumstances (Sorahan et al., 1995; Sorahan and Lancashire, 1997; Garcia-Esquinas et al., 2014). Some epidemiological evidence has also suggested an association between cadmium exposure and prostate cancer (Shigematsu et al., 1982; van der Gulden et al., 1995), kidney cancer (Mandel et al., 1995), bladder cancer (Siemiatycki et al., 1994), pancreatic cancer (Kriegel et al., 2006; Luckett et al., 2012; Garcia-Esquinas et al., 2014; Chen et al., 2015), breast cancer, and endometrial cancer (Cho et al., 2013).

Chromium Human exposure to chromium (VI) compounds can occur through inhalation of ambient air, ingestion of water, or dermal contact with products that contain chromium (VI) compounds, such as pressure-treated wood. Chromium has multiple oxidation states—from −2 to +6; however, the most common forms are the trivalent (III) and hexavalent (VI) forms. With regard to carcinogenicity, chromium III does not exhibit carcinogenicity in laboratory animals whereas chromium VI has been shown to be positive for genotoxicity and carcinogenicity in a variety of bioassays (Langard, 1988; IARC, 1990). Chromium VI compounds cause genetic damage including gene mutations and DNA damage in bacteria. Several chromium VI compounds also caused mutations in yeast and insects. Several chromium VI compounds caused genetic damage in cultured human and other animal cells and in experimental animals exposed in vivo, including sister chromatid exchange (SCE), chromosomal aberrations, and cell transformation. Chromosomal aberrations, SCE, and aneuploidy were observed in workers exposed to chromium VI compounds (IARC, 1990). Chromium VI (calcium chromate, chromium trioxide, sodium dichromate, lead chromates, strontium chromate, or zinc chromates) exposure of rats following inhalation, intrabronchial, intrapleural, intratracheal, intramuscular, or subcutaneous administration resulted in benign lung tumors and malignant lung tumors were observed in rats in a number of studies. In mice, calcium chromate caused benign lung tumors and chromium trioxide caused malignant lung tumors. Exposure of hamsters, guinea pigs, and rabbits to chromium (VI) compounds by intratracheal instillation did not cause lung tumors (IARC, 1980, 1990). Although the mechanisms of action for chromium VI carcinogenicity remain unresolved, it has been proposed that chromium VI may induce lung tumor following inhalation exposure via direct interaction with DNA causing mutations (mutagenic mode of action; McCarroll et al., 2010) or induction of oxidative stress following reduction to chromium III (non-mutagenic mode of action; Proctor et al., 2014).

Hexavalent chromium (chromium VI) compounds have been classified by IARC as known human carcinogens based on data from animal studies and human epidemiological studies (IARC 1990, 2012). Human epidemiological studies have consistently reported increased risks of lung cancer among chromate workers. Chromate workers are exposed to a variety of chromium compounds, including chromium (VI) and trivalent (III) species. In addition, an increased risk of a rare cancer of the sinonasal cavity was observed in these workers (IARC, 1990). Some studies suggested that exposure to chromium among workers such as chromium-exposed arc welders, chromate pigment workers, chrome platers, and chromium tanning workers may also be associated with stomach cancer (Welling et al., 2015), leukemia, and bone cancer (Costa, 1997).

Nickel Nickel is present in air, water, food, and consumer products; therefore, people can be exposed to nickel through food, nickel alloys, and nickel-plated materials, such as coins, steel, and jewelry. Occupational exposure to nickel occurs mainly through inhalation of dust particles and fumes or through dermal contact. Nickel workers can also ingest nickel-containing dusts. Many studies in cultured rodent and human cells have shown that a variety of nickel compounds, including both soluble and insoluble forms of nickel, exhibit genotoxicity, producing DNA strand breaks, mutations, chromosomal damage, cell transformation, increasing oxidative reactive species, and modulation of DNA repair. Soluble nickel salts can be complete carcinogens and/or initiators of carcinogenesis (Kasprzak et al., 1990; Diwan et al., 1992). In rats and mice, inhalation or intratracheal instillation of nickel subsulfide or nickel oxide produced dose-related increases of benign and malignant lung tumors (IARC, 1990, 2012; NTP, 1996). Inhalation of nickel compounds also caused malignant and benign pheochromocytoma (NTP, 1996), and adrenal cortex tumors in rats (Oller et al., 2008). Short-term intraperitoneal exposure during gestation to soluble nickel salt induced malignant pituitary tumors in the offspring. Additionally, exposure to nickel acetate through the placenta followed by exposure of the offspring to barbital (a known tumor promoter) produces tumors of the kidney (renal cortical and pelvic tumors) (Diwan et al., 1992). In adult rats, injection of soluble nickel salts followed by exposure to a promoting carcinogen

resulted in kidney cancer (renal cortical adenocarcinomas) that frequently metastasized to the lung, liver, and spleen (Kasprzak et al., 1990). The carcinogenic properties of metallic nickel are thought to be due to ionic nickel, which can slowly dissolve in the body from nickel compounds.

Nickel compounds are classified as known human carcinogens (11th RoC) based on animal data and sufficient evidence of carcinogenicity from human studies. The IARC (1990, 2012) evaluation of nickel and nickel compounds concluded that nickel compounds are carcinogenic to humans based on sufficient evidence for the carcinogenicity of nickel compounds in the nickel refining industry and very strong evidence of carcinogenicity of a variety of nickel compounds in experimental studies in rodents. Several cohort studies of workers exposed to various nickel compounds showed an elevated risk of death from lung and nasal cancers (IARC, 1990, 2012). An excess risk of lung and nasal cancer was seen in nickel refinery workers exposed primarily to soluble nickel compounds (Andersen et al., 1996; Grimsrud et al., 2002, 2003, 2005; Pavela et al., 2017). In addition, a recent meta-analysis revealed that high serum nickel levels were associated with increased risk of breast cancer (Yu and Zhang, 2017), while high soil levels of nickel were correlated with high prevalence of esophageal and oral cancer (Lee et al., 2016; Pavela et al., 2017).

Lead Lead is a naturally occurring metal that can be found in air, soil, and water. Humans can be exposed to lead via use of fossil fuels including past use of leaded gasoline, some types of industrial facilities, and past use of lead-based paint in homes. Children are more sensitive to the damaging effects of lead than adults. They can be exposed to lead eating and drinking food or water containing lead, or inhaling lead dust from lead-based paint or lead-contaminated soil or from playing with toys with lead paint. Lead compounds do not appear to cause genetic damage directly, but may do so through several indirect mechanisms, including inhibition of DNA synthesis and repair, oxidative damage, and interaction with DNA-binding proteins and tumor-suppressor proteins (NTP, 2003). Lead has exhibited conflicting results concerning its genotoxicity; it does not cause mutations in bacteria, but does cause chromosomal aberrations in vitro and in vivo, and causes DNA damage in vivo and in cell-free systems, whereas in mammalian systems, conflicting results have been observed. Lead also inhibits the activity of DNA and RNA polymerase in cell-free systems and in mammalian cell cultures. Conflicting results were observed for SCE and micronucleus formation in mammalian test systems.

In studies with laboratory animals, carcinogenicity has been observed for soluble (lead acetate and lead subacetate) and insoluble (lead phosphate, lead chromate) inorganic lead compounds as well as for tetraethyl lead (an organic lead compound), following exposure via oral intake or injection, and in offspring exposed via the placenta or lactation. Although kidney tumors (including adenomas, carcinomas, and adenocarcinomas) were most frequently associated with lead exposure, tumors of the brain, hematopoietic system, and lung were reported in some studies (IARC, 1980, 1987, 2006; Waalkes et al., 1995). Lead also appears to function as a tumor promoter, leading to increased incidence in kidney tumors initiated by *N*-ethyl-*N*-hydroxyethylnitrosamine and *N*-(4′-fluoro-4-biphenyl)acetamide (IARC, 1980, 1987, 2006). The mechanisms by which lead causes cancer are not understood.

Lead and lead compounds are classified as reasonably anticipated to be human carcinogens based on limited evidence from studies in humans and sufficient evidence from studies in experimental animals by NTP (11th RoC, 2004) and Group 2A carcinogen by IARC (2006). Lead exposure has been associated with increased risk of lung, stomach, and bladder cancer in diverse human populations (Fu and Boffetta, 1995; Steenland and Boffetta, 2000; NTP, 2003; IARC, 2006). Epidemiological studies link lead exposure to increased risk for lung and stomach cancer. However, most studies of lead exposure and cancer reviewed had limitations, including poor exposure assessment and failure to control for confounding factors.

Modifiers of Chemical Carcinogenic Effects

Genetic and environmental factors have a significant impact on the way in which individuals and/or organisms respond to carcinogen exposure. As with most genes, enzymes that metabolize carcinogens are expressed in a tissue-specific manner. Within tissues, the enzymatic profile can vary with cell type or display differential localization within cells. Further, carcinogen metabolizing enzymes are differentially expressed among species. These differences may represent an underlying factor explaining the differential responses to chemical carcinogens across species.

The expression of many carcinogen metabolizing enzymes is highly inducible by foreign chemicals. Compounds such as benzo(*a*)pyrene induce P450 isozymes CYP1A1 and 1A2, enzymes that display catalytic activity toward a number of polycyclic aromatics. A number of other enzymes, for example, GST isozymes, uridine diphosphate glucuronyltransferases (UDPGTs) are also induced by PAHs, thus the net result is enhanced metabolism of PAHs. Numerous other chemical carcinogens are potent inducers of drug metabolizing enzymes; examples include chemicals such as phenobarbital, dichlorodiphenyltrichloroethane (DDT), ethanol, 17β-estradiol, PPARα agonists, each of these results in the upregulation of a distinct set of phase I and phase II enzymes (see Chap. 6). Some carcinogens also produce inhibitory effects on drug metabolism enzymes, and could either increase the half-life of a chemical carcinogen or prevent or delay the formation of active metabolites of carcinogens.

Polymorphisms in Carcinogen Metabolism and DNA Repair

Genetic polymorphisms arise from human genetic variability. A genetic polymorphism is when a gene has more than one allele. In assessing variability in the human genome project it was found that base variations occurred at approximately once in every 1000 base pairs. Therefore, there may be over one million genetic variations between any two individuals. A single nucleotide polymorphism (SNP) is a variant in DNA sequence found in greater than 1% of the population (Fig. 8-27). Thus, by definition, changes in DNA sequence goes from mutation to polymorphism when a unique genotype is seen in over 1% of the population. Over 3 million candidate SNPs have been identified to date with up to 10 million being estimated to be present within the human genome. In carcinogenesis, genetic polymorphisms may account for the susceptibility of some individuals to certain cancers. In particular, SNPs of genes involved in carcinogen metabolism (activation and detoxification) and DNA repair have received considerable attention. A number of polymorphisms have been described in carcinogen metabolizing enzymes, with certain alleles linked to altered risk of selective cancers (Boddy and Ratain, 1997; Naoe et al., 2000). Glutathione-*S*-transferases (GSTs), which are involved in detoxification of many chemical carcinogens and also in the remediation of oxidative stress, are highly polymorphic in humans. Polymorphisms of the GSTM1 phenotype have been related to bladder, gastric, and lung cancer in humans (Tsuchida and Sato, 1992; Welfare et al., 1999). Individuals expressing the GSTM1 null genotype have a 1.5-fold higher risk for bladder cancer and 1.7-fold increase risk for gastric

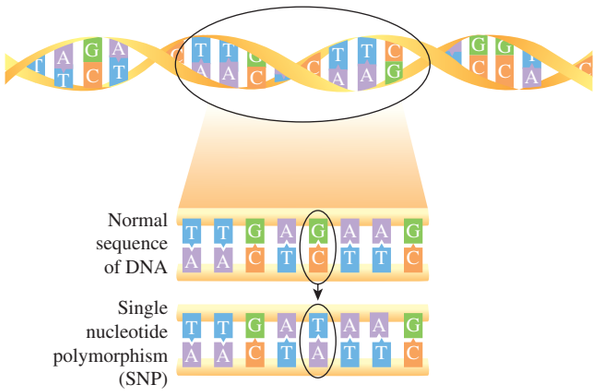

Figure 8-27. *Example of a single nucleotide polymorphism in DNA.* Single nucleotide polymorphisms are instances in which a single nucleotide is changed within a DNA sequence.

cancer compared to individuals expressing the genotype (Risch et al., 2001; Ates et al., 2005). The GSTM1 isoform is of particular important in carcinogenesis because this isoform exhibits the highest reactivity toward epoxides. GSTT1 isoform null individuals show a threefold increase risk in breast cancer, a 1.6-fold increase in gastric cancer, and a fourfold increase in liver cancer compared to individuals having the genotype (Bosch et al., 2006).

Similarly in women (nonsmokers) with lung cancer, a higher level of PAH DNA adducts have been detected. Higher DNA adduct levels are also found to be associated with the expression of the cytochrome P4501A1 (*CYP1A1*) gene, which bioactivates PAHs (Han et al., 2003). An increase in benzo(*a*)pyrene DNA adduct levels correlate with increased expression of the CYP1A1. DNA repair genes, in particular oxidative DNA repair, OGG1, involved in repair of 8-OHdG–induced damage, have been linked to an increase in lung cancer in individuals with lower OGG1 expression (Goode et al., 2002; Klaunig et al., 2011).

In the case of prostate cancer, studies have suggested roles for a number of candidate SNPs. Recent evidence suggests that the presence of a genetic variant that is more prevalent in African American men that is less effective of clearing reactive oxygen species. Examples of candidate genes that likely contribute to prostate cancer carcinogenesis include the androgen receptor gene, steroid synthesis, and metabolism genes (*CYP17*, *CYP1B1*, *CYP3A4*, *CYP3A5*, *CYP3A43*, *SD5A2*, *HSD3B1*, *HSD3B2*, *CYP19*), transmembrane drug efflux gene (*ABCG2*), and reactive oxygen species metabolizing genes (*MnSOD*, *APE1*, *XRCC1*, *GSTP1*; Dong, 2005). Individually, polymorphisms in each of these genes have been associated with an increased risk of prostate cancer.

The importance of SNPs, cancer susceptibility, and cancer risk are illustrated in Table 8-16. If exposure to a chemical carcinogen is low and the genetic susceptibility for genes related to the carcinogenic activity is low, then the risk for cancer will also be low. If exposure to a chemical carcinogen is high but the genetic susceptibility is low, then the risk for cancer development is likely to be low. However, if the genetic susceptibility is high, then exposure to a chemical carcinogen will result in a higher risk for cancer development.

Proto-Oncogenes and Tumor-Suppressor Genes

Proto-oncogenes and tumor-suppressor genes play a key role in cancer induction. These genes encode a wide array of proteins that function to control cell growth and proliferation. Common characteristics of oncogenes and tumor-suppressor genes are shown in Table 8-17. Mutations in both oncogenes and tumor-suppressor genes contribute to the progressive development of human cancers. Accumulated damage to multiple oncogenes and/or tumor-suppressor genes can result in altered cell proliferation, differentiation, and/or survival of cancer cells (Croce, 2008; Huff, 2011).

Table 8-16

Carcinogen Exposure and Cancer Risk in Humans

EXPOSURE	SUSCEPTIBILITY (GENOTYPE)	RESULT (DISEASE)
↓	↓	Low risk
↑	↓	Low risk
↓	↑	Moderate risk
↑	↑	High risk

Table 8-17

Characteristics of Proto-Oncogenes, Cellular Oncogenes, and Tumor Suppressor Genes

PROTO-ONCOGENES	ONCOGENES	TUMOR SUPPRESSOR GENES
Dominant	Dominant	Recessive
Broad tissue specificity for cancer development	Broad tissue specificity for cancer development	Considerable tissue specificity for cancer development
Germline inheritance rarely involved in cancer development	Germline inheritance rarely involved in cancer development	Germline inheritance frequently involved in cancer development
Analogous to certain viral oncogenes	No known analogues in oncogenic viruses	No known analogues in oncogenic viruses
Somatic mutations activated during all stages of carcinogenesis	Somatic mutations activated during all stages of carcinogenesis	Germline mutations may initiate, but mutation to neoplasia occurs only during progression stage

Retroviruses Evidence that specific genes (oncogenes) could cause cancer first came from studies showing sarcomas could be produced in healthy chickens by injecting them with cell-free extracts derived from chicken tumors (Rous, 1911). The transforming agent in the filtrate eventually was shown to be an RNA-type tumor virus, the *Rous sarcoma virus* (RSV) that is capable of transforming a normal cell and produce sarcomas within weeks of injection (Temin and Rubin, 1958). The genome of RSV and other retroviruses consists of two identical copies of mRNA, which is

then reverse transcribed into DNA and incorporated into the host-cell genome. Oncogenic transforming viruses such as RSV contain the v-*src* gene, a gene required for cancer induction by these viruses. It was later demonstrated that normal cells from chickens and other species contain a gene closely related to v-*src* in RSV; the normal "proto-oncogene" commonly is distinguished from the viral gene by the prefix "c" (c-*src*; Oppermann et al., 1979). This discovery showed that cancer may be induced by the action of normal, or nearly normal, genes.

DNA Viruses Six major classes of DNA tumor viruses have been identified: simian virus 40 (SV40), polyoma virus, hepatitis B virus, papilloma viruses, adenoviruses, herpes viruses, and poxviruses. Unlike retroviral oncogenes, which are derived from normal cellular genes and have no function for the virus, the known oncogenes of DNA viruses are integral parts of the viral genome required for viral replication. SV40 or polyoma viruses are not capable of inducing tumors in their natural host species (monkey and mice, respectively). Infection by small DNA viruses is lethal to most non-host animal cells; however, a small proportion integrates the viral DNA into the host-cell genome. The cells that survive infection become permanently transformed due to the presence of one or more oncogene in the viral DNA. For example, SV40 codes for the large T antigen, which alone is capable of inducing transformation (Fried and Prives, 1986). Both SV40 and polyoma viruses use the host-cell's DNA synthetic apparatus for their own replication. Papilloma viruses can infect and cause tumors in rabbits, cows, and humans (Lancaster and Olson, 1982). Of the human papilloma viruses, types 6, 10, and 11 are associated with genital warts, whereas types 16, 18, 31, and 33 are associated with human cervical cancers (Vousden, 1989). Herpes viruses are complex and are capable of producing tumors in frogs, chickens, monkeys, and humans (Rapp, 1974). Included among this class is the Epstein–Barr virus, a causative agent in the development of Burkett B-cell lymphomas and in nasopharyngeal carcinoma (de-Thé et al., 1978), and is mediated by genes encoding *EBNA-1, EBNA-2*, and *latent membrane protein* (Fahreus et al., 1990). Adenoviruses affect host and non-host cells differently; in host cells, infection causes lysis whereas in non-host cells, infection results in transformation via *E1A* and *E1B* genes (Pettersson and Roberts, 1986). Hepatitis B viruses specifically infect the liver of ducks, woodchucks, and squirrels, and are strongly associated with liver cancer development in humans; infected individuals exhibit a >100-fold risk for cancer development (Synder et al., 1982). Hepatitis B gene X is thus far the main gene implicated in the transformation process (Kim et al., 1991). Poxviruses (e.g., Yaba monkey virus, Shope fibroma virus) replicate in the cytoplasm of infected cells and produce benign tumors (Niven et al., 1961).

Proto-Oncogenes An oncogene is a gene encoding a protein that is capable of transforming cells in culture or inducing cancer in animals. Of the known oncogenes, the majority appear to have been derived from normal genes (i.e., proto-oncogenes), and are involved in cell signaling cascades (Table 8-18). Because most proto-oncogenes are essential for maintaining viability, they are highly conserved evolutionarily. It has been clearly demonstrated that altered expression of these genes results in unregulated control of cell growth. Activation of proto-oncogenes arises through mutational events occurring within proto-oncogenes (Alitalo and Schwab, 1986; Bos, 1989). It has been recognized that a number of chemical carcinogens are capable of inducing mutations in proto-oncogenes (Balmain and Pragnell, 1983; Hoenerhoff et al., 2009).

Table 8-18
Examples of Oncogenes and Cancer Association

	ONCOGENE	NEOPLASM
Tyrosine kinases	EGFR	Squamous cell carcinoma
	PDGF	Lung carcinoma
		Astrocytoma
	v-fms	Sarcoma
	v-kit	Sarcoma
	v-ros	Sarcoma
	v-fgr	Sarcoma
	v-fps	Sarcoma
	Src	Colon carcinoma
	Neu	Breast carcinoma
		Neuroblastoma
	Ret	Thyroid carcinoma
	Trk	Colon carcinoma
Serine/threonine kinases	v-raf	Sarcoma
	v-mos	Sarcoma
G proteins	H-Ras	Colon and lung carcinoma
	K-Ras	Melanoma, acute myeloid leukemia (AML), and thyroid carcinoma
	N-Ras	Carcinoma and melanoma
	NF-1	Neurofibromas
Nuclear proteins	c-Myc	CML, Burkitt lymphoma
	N-Myc	AML, breast and lung carcinoma
	L-Myc	Neuroblastoma and lung carcinoma
	v-myb	Lung carcinoma
	v-jun	Sarcoma
	v-fos	Osteosarcoma
	v-rel	Leukemia
	v-ets	Myeloblastosis
	v-erbA	Erythroblastosis

Several oncogene products are associated with growth factors. The *sis* oncogene encodes for platelet-derived growth factor (PDGF), which consists of type A and B chains. Active PDGF can consist of homo- or heterodimers of the A and B chains. Only cells that express the PDGF receptor are susceptible to transformation by the *sis* oncogene (Dooliter et al., 1983). Fibroblast growth factor (FGF), epidermal growth factor (EGF), and the *wnt* family also have oncogenes that encode for their production (Burgess et al., 1989; Nusse and Varmus, 1992). Enhanced expression of these growth factor genes leads to transformation of cultured cells. In addition, lung carcinomas and astrocytomas in humans express both PDGF and its receptor.

In order for the growth factors listed above to induce cell growth, the cell must also express the appropriate growth factor receptors. Ligand binding to receptors in many cases results in the activation of signaling cascades, of which a number have protein kinase activity. Protein kinases can phosphorylate at tyrosine, serine, or threonine residues. Several oncogene products have been

identified that have tyrosine kinase activity (e.g., *src, fps, fgr, fms, kit,* and *ros*; Collett and Erikson, 1978). Growth factor receptors including EGF, PDGF, insulin, insulin-like growth factor, and FGF have tyrosine activity (Wells, 1999). An extensive number of protein kinases are serine or threonine kinases, some of which can be activated in tumor cells and lead to transformation. The protein kinase C family consists of serine/threonine kinases (Nishizuka, 1988). This family of proteins participates in the inositol–phospholipid second messenger pathway and can be activated by calcium and diacylglycerol, and phorbol ester tumor promoters. *Raf* and *mos* oncogenes are other examples of serine threonine kinases that interact with mitogen activated kinase pathways, leading to enhance the expression of "immediate-early" genes such as Myc, and Fos/Jun heterodimers, and ultimately lead to enhanced cell growth (Su and Karin, 1996).

Guanine nucleotide binding proteins is a subset of the guanosine-5′-triphosphate (GTP) superfamily. The primary oncogenic members of this family are the *ras* genes (e.g., *Ha-*, *Ki-*, and *n-ras*), which were initially found in murine retroviruses, and are frequently activated in human tumors and in chemically induced tumors in rodent models (McCormick, 1994). The three ras forms differ by only 20 amino acids and have a conserved cytosine-186, which is a site for posttranslational modification by a farnesyl, isoprenyl group, a modification that is needed for membrane localization (Hancock et al., 1989). Mutations in *ras* affect the association of the Ras with GTP, and because Ras is active when GTP is bound, constitutive Ras activation is often seen with mutated forms of *ras*. Many mutation sites are associated with activation of *ras* and include codons 12, 13, 61, 116, 117, 119, and 146 (de Vos et al., 1988). Although a dominant gain-of-function mutation in the *ras* gene converts it into an oncogene, a recessive loss-of-function mutation in the *NF1* gene also leads to constitutive Ras activation. *NF1* encodes a GTPase-activating enzyme (GAP) that accelerates hydrolysis of GTP and the conversion of active GTP-bound Ras to inactive GDP-bound Ras. The loss of GAP leads to sustained Ras activation of downstream signal transduction proteins. Individuals with neurofibromatosis have inherited a single mutant *NF1* allele; subsequent somatic mutation in the other allele leads to formation of neurofibromas.

In addition to acting at the receptor level, some oncogene products are nuclear transcription factors and thus cause alteration of gene expression. One of the first to be identified was the erbA oncogene product, which is an altered form of the thyroid hormone receptor (Damm et al., 1989). This altered form is unable to bind thyroid hormone and allows the oncogene protein to act in a dominant-negative manner, functioning as a constitutive repressor of normal expression of genes regulated by thyroid hormone. Another family of oncogenes encode for the AP-1 transcription factor, a complex consisting of *jun* and *fos*, as well as Jun family members with homology to c-jun (Jun B and Jun D) (Chiu et al., 1988; Vogt, 2001). Phorbol esters and several other tumor-promoting compounds are able to rapidly induce gene expression of both *fos* and *jun*. Activation of both *fos* and *jun* results in the constitutive expression of the activator protein 1 (AP-1) transcription factor and sustained stimulation of cell growth signals. The *myc* family (*c-myc, N-myc*, and *L-myc*) encode for transcription factors that are found activated in a number of tumor types (Marcu et al., 1992).

Tumor-Suppressor Genes

Retinoblastoma (Rb) Gene In contrast to oncogenes, the proteins encoded by most tumor-suppressor genes act as inhibitors of cell proliferation or cell survival (Table 8-19). The prototype tumor-suppressor gene, Rb, was identified by studies of inheritance of retinoblastoma. Loss or mutational inactivation of Rb contributes to the development of a wide variety of human cancers. In its unphosphorylated form, Rb binds to the E2 factor (*E2F*) transcription factors preventing E2F-mediated transcriptional activation of a number of genes whose products are required for DNA synthesis. In addition, the Rb–E2F complex acts as a transcriptional repressor for many of these same genes (Chellappan et al., 1991). During the early G_1 phase of the cell cycle, Rb is an unphosphorylated state, but becomes phosphorylated during late G_1, causing dissociation from E2F—a process that allows E2F to induce synthesis of DNA replication enzymes, resulting in a commitment into the cell cycle. Rb phosphorylation is initiated by an active cyclin-dependent kinase 4 (Cdk4)–cyclin D complex and is completed by other cyclin-dependent kinases (Sherr, 1993; Weinberg, 1995). Most tumors contain an oncogenic mutation of one of the genes in this pathway such that cells enter the S phase of the cell cycle in the absence of the proper extracellular growth signals that regulate Cdk activity. In addition, Rb is bound and inactivated by the E1A protein of the adenoviruses (Whyte et al., 1988) and also by the large T antigen of SV40 and the E7 protein of the papilloma virus, suggesting that the elimination of Rb function may be an important mechanism in tumor development by viruses and/or mutations induced by chemical carcinogens.

Table 8-19

Examples of Tumor Suppressor Genes and Cancer Association

TUMOR SUPPRESSOR	DISORDER	NEOPLASM
Rb1	Retinoblastoma	Small-cell lung carcinoma
p53	Li–Fraumeni syndrome	Breast, colon, lung cancers
BRCA1	Unknown	Breast carcinoma
WT-1	Wilms tumor	Lung cancer
p16	Unknown	Melanoma

p53 Gene The p53 protein is a tumor-suppressor gene that is essential for the checkpoint control and arrests the cell cycle in cells with damaged DNA in G_1. Cells with functional p53 arrest in G_1 when exposed to DNA-damaging agents such as irradiation, whereas cells lacking functional p53 are unable to block the cell cycle. p53 is activated by a wide array of stressors including UV light, γ irradiation, heat, and several carcinogens. DNA damage by γ irradiation or by other stresses leads to the activation of certain kinases, including ataxia telangiectasia mutated (ATM), which is encoded by the gene mutated in ataxia telangiectasia and a DNA-dependent protein kinase. Phosphorylation of p53 by these and other kinases results in stabilization of p53 and an increase in cell content of this protein (Finlay et al., 1989). The active form of p53 is a tetramer of four identical subunits. A missense point mutation in one *p53* of the two alleles in a cell can abrogate almost all p53 activity because virtually all the oligomers will contain at least one defective subunit and such oligomers cannot function as a transcription factor. Oncogenic *p53* mutations thus act as "dominant negatives," in contrast to tumor-suppressor genes such as Rb.

Virtually, all p53 mutations abolish their ability to bind to specific DNA sequences and activate gene expression (El-Deiry et al., 1992). The transcription of cyclin-kinase inhibitor p21, which binds to and inhibits mammalian G_1 Cdk–cyclin complexes, is induced by p53. As a result, cells with damaged DNA are arrested in G_1 until the damage is repaired and the levels of p53 and p21 fall; the cells then can progress into the S phase. In most cells, accumulation of p53 also leads to induction of proteins that promote apoptosis, and, therefore, would prevent proliferation of cells that are likely to accumulate multiple mutations. When the p53 checkpoint control does not operate properly, damaged DNA can replicate, producing mutations and DNA rearrangements that contribute to the development of transformed cells. Proteins that interact with and regulate p53 are also altered in many human tumors. The gene encoding one such protein, MDM2 (murine double minute 2 homolog), is amplified in many sarcomas and other human tumors that maintain functional p53 (Leach et al., 1993). Under normal conditions, MDM2 binds the N-terminus of p53, repressing the ability of p53 to activate transcription of p21 and genes mediating p53 degradation. Thus, MDM2 normally inhibits the ability of p53 to block at G_1 or induce apoptosis. Enhanced MDM2 levels in tumor cells therefore results in decreased functional p53 and prevents p53 from growth arrest in response to irradiation or chemical carcinogens. For example, benzo(*a*)pyrene produces inactivating mutations at codons 175, 248, and 273 of the p53 gene in cultured cells; these same positions are mutational hot spots in human lung cancer (Hollstein et al., 1991). Aflatoxin exposure induces a G to T transversion at codon 249 of p53, and methyl-*N*′-nitro-*N*-nitrosoguanidine (MNNG) can alter methylation of DNA leading to inactivation of p53 (Bressac et al., 1991).

BRCA1 Gene Genetic analysis of breast tumors has revealed a hereditary predisposition for breast cancer linked to BRCA1 (breast cancer gene 1), a tumor-suppressor gene. Mutation of a single BRCA1 allele results in a 60% probability of developing breast cancer by age 50. In families transmitting the mutant BRCA1 allele, the normal allele is often absent in tumors. A number of investigators have shown that germ line mutations lead to loss of function of the BRCA1 gene, perhaps by acting as a transcription factor through binding at a zinc finger domain. However, no mutations have been observed in sporadic breast cancers (Futreal et al., 1994), suggesting that BRCA1 gene silencing may occur through nonmutational mechanisms.

Wilms Tumor Gene (WT1) Wilms tumor occurs in the developing kidney at a rate of approximately one per 10,000 children. The WT1 gene is considered to be responsible for tumor development and is thought to function as a transcription factor (Hastie, 1994). The DNA-binding region of the WT1 gene contains four zinc finger domains, and binds a consensus sequence shared with EGR1; however, WT1 acts as a transcriptional repressor at this site (Rauscher et al., 1990). Similar to p53, WT1 mutant alleles act in a dominant-negative manner.

p16 Gene The group of proteins that function as cyclin-kinase inhibitors play an important role in cell cycle regulation. Mutations, especially deletions of the p16 gene, that inactivate the ability of p16 to inhibit cyclin D–dependent kinase activity are common in several human cancers including a high percentage of melanomas (Kamb et al., 1994). Loss of p16 would mimic cyclin D1 overexpression, leading to Rb hyperphosphorylation and release of active E2F transcription factor. Thus, p16 normally acts as a tumor suppressor. As with the BRCA1 gene, relatively few mutations have been found in this gene, and some researchers have speculated that epigenetic mechanisms such as gene silencing by DNA methylation may occur during tumorigenesis (Merlo et al., 1995).

Hormesis, Dose Response, and Carcinogenesis

Hormesis is defined as a dose–response curve in which a U, J, or inverted U-shaped dose–response is observed, with low-dose exposures often resulting in beneficial rather than harmful effects (Calabrese, 2002) (Fig. 8-28). One of the first reports establishing a hormetic response was observed with ionizing radiation, in which it was hypothesized to be due to adaptation to background radiation exposure, as well as enhanced metabolism and detoxification (Calabrese, 2002; Parsons, 2003). Numerous examples exist that provide evidence for U- and J-shape dose relationships to different biomarkers of carcinogenesis, both for initiating and promoting carcinogens. For example, low-dose styrene treatment resulted in a decrease of chromosomal aberrations (Camurri et al., 1983). A reduction in DNA strand breaks in human keratinocytes was seen following low-dose exposure to *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine, whereas high doses were greatly elevated compared to controls (Kleczkowska and Althaus, 1996). Several chronic bioassays for carcinogenicity in rats and mice have demonstrated a negative correlation between proliferative hepatocellular lesions and lymphomas at low- and medium-dose levels (Young and Gries, 1984). TCDD at hepatocarcinogenic doses resulted in a dose-dependent reduction in mammary and uterine tumors (Kociba et al., 1978). TCDD also reduces tumor incidence after exposure to low doses of radiation and selenium (Nordberg and Andersen, 1981; Pollycove and Feinendegen, 2001). Evidence for a U-shaped dose–response curve has also been demonstrated for phenobarbital (Kitano et al., 1998; Ito et al., 2003; Kinoshita et al., 2003). These investigators have shown that phenobarbital promoted the growth of diethylnitrosamine-induced hepatic lesions at doses between 60 and 500 ppm, whereas doses between 1 and 7.5 ppm decreased lesion growth, hepatocellular carcinoma, and tumor multiplicity. Other examples include DDT (Sukata et al., 2002; Kushida et al., 2005) and α-benzene hexachloride (Puatanachokchai et al., 2006).

Adaptive mechanisms have been proposed to explain the hormetic effects observed by chemical carcinogens. When experimental animals are exposed to chemicals, the initial response is an adaptive response to maintain homeostasis (Calabrese, 2002; Kakehashi et al., 2013). Adaptive responses usually involve actions of the chemical on cellular signaling pathways that lead to changes in gene expression, resulting in enhanced detoxification and excretion of the chemical as well as preserving the cell cycle and programmed cell death. It has been proposed that following

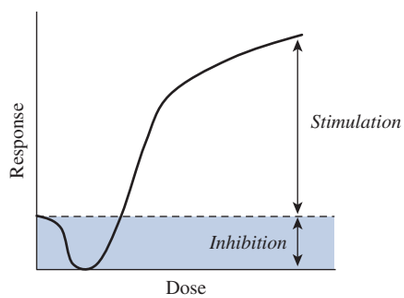

Figure 8-28. *Hormesis curve.*

very low doses of chemicals, the upregulation of these mechanisms overcompensates for cell injury such that a reduction in tumor promotion and/or tumor development is seen, and would explain the U- or J-shaped response curves obtained following carcinogen exposure.

A common feature of chemical carcinogens for which hormetic effects have been proposed is the formation of reactive oxygen species and the induction of cytochrome P450 isoenzymes. Inhibition of carcinogenesis by low levels of phenobarbital has been postulated to involve the suppression of 8-OHdG generation and cellular proliferation within areas of glutathione-*S*-transferase pi (GST-P) positive foci, possibly related to enhanced expression of the gene encoding the enzyme oxoguanine glycosylase one (Ogg1), which is responsible for the repair of 8-OHdG lesions (Kinoshita et al., 2003; Fukushima et al., 2005). Another explanation for the suppressive effect of low-level phenobarbital on the development of preneoplastic lesions involves the stimulation of hepatic drug metabolizing enzymes, which detoxify carcinogens (Pitot et al., 1987). In a low-dose phenobarbital study, cDNA microarray analysis resulted in a suppression of mRNA expression of MAP kinase p38, JNK1, 2, and other intracellular kinases (Kinoshita et al., 2003). Thus, suppression of signal transduction modulators appears to be involved in the inhibitory effect of phenobarbital on cell proliferation.

Chemoprevention

The study of chemicals that prevent, inhibit, or slow down the process of cancer is referred to as chemoprevention. This is in contrast to chemotherapy where drugs are used to target an already formed neoplasm with the purpose of selectively killing the cancer cells. A number of chemicals, including drugs, antioxidants, foodstuffs, and vitamins have been found to inhibit or retard components of the cancer process (Table 8-20) in both in vitro and in vivo models (Stoner et al., 1997). Cancer chemoprevention involves the administration or inclusion in the diet of natural or synthetic chemicals in an attempt to prevent, halt, or reverse the process of carcinogenesis. An assumption in chemoprevention is that treating early stages of the malignant process will halt or delay the progression to neoplasia. Cancer chemopreventive chemicals may function at one or more of the stages of the carcinogenesis process, functioning via one or several mechanisms. These include inhibition of carcinogen formation, blocking agents, and/or as suppressing agents (Table 8-20). Blocking agents serve to prevent the metabolic activation of genotoxic or non-genotoxic carcinogens by either inhibiting their metabolism or enhancing the detoxification mechanisms. In the case of reactive oxygen species generation by a carcinogen, antioxidants, such as, *N*-acetylcysteine, or vitamins E, A, and C serve as blocking agents by trapping the oxidative species before it can induce cellular damage. The drug oltipraz induces phase II

Table 8-20

Classes of Chemopreventive Agents

INHIBITORS OF CARCINOGEN FORMATION	EXAMPLES
Reductive acids	Ascorbic acid
Phenols	Caffeic acid, ferulic acid, gallic acid
Sulfhydryl compounds	*N*-Acetylcysteine
Amino acids	Praline, thioproline
Blocking Agents	
Inhibition of cytochrome P450	Dithiocarbamates, ellagic acid, diallyl sulfide, isothiocyanates
Induction of cytochrome P450	Indole-3-carbinol, β-naphthoflavone
Induction of phase II enzymes	
Glutathione *S*-transferase	Allyl sulfides, dithiolethiones, isothiocyanates
UDP-glucuronyltransferase	Polyphenols
Glutathione peroxidase	Selenium
Scavenge electrophiles	Ellagic acid, *N*-acetylcysteine
Scavenge free radicals	Sodium thiosulfate, polyphenols, vitamin E
Increase overall levels of DNA repair	Vanillin
Increase poly(ADP-ribosyl) transferase	*N*-Acetylcysteine
Suppress error-prone DNA repair	Protease inhibitors
Suppressing Agents	
Inhibit polyamine metabolism	DRv10, polyphenols, substituted putrescines
Induce terminal cell differentiation	Calcium, retinoids, vitamin D_3
Modulate signal transduction	Glycyrrhetinic acid, nonsteroidal anti-inflammatory drugs (NSAIDs), polyphenols, retinoids
Modulate hormonal/growth factor activity	
Inhibit oncogene activity	NSAIDs, retinoids, tamoxifen
Promote intracellular communication	Genistein, NSAIDs, monoterpenes
Restore immune response	Carotenoids, polyphenols, retinoids
Induce apoptosis	NSAIDs, selenium, vitamin E
Correct DNA methylation imbalances	Butyric acid, genistein, selenium, sulindac sulfone, retinoids
Inhibit basement membrane degradation	Folic acid, choline, methionine
Inhibit arachidonic acid metabolism	Protease inhibitors
	Glycyrrhetinic acid, *N*-acetylcysteine, NSAIDs, polyphenols

enzymes; in particular, glutathione-*S*-transferase by activating the transcription factor Nrf2, and has been shown to reduce the carcinogenicity of aflatoxin B1 by enhancing its detoxification (Jacobson et al., 1997). Nrf2 is a transcription factor that positively regulates the basal and inducible expression of a number of cellular protective genes. (Klaassen and Reisman, 2010). Activation of Nrf2 has been shown to increase the expression of genes involved in the detoxification of electrophiles and oxidative stress (Reisman et al. 2009a, b). Chemopreventive chemicals increase tissue resistance function on the target tissue, usually an early preneoplastic lesion by increasing tissue maturation and/or decreasing cell proliferation. Suppressing chemicals induce tissue differentiation, may counteract oncogenes, enhance tumor-suppressor gene activities, inhibit proliferation of premalignant cells, or modify the effect of the carcinogen on the target tissue. Retinoic acid is a classic agent that functions by inducing target tissue differentiation. Similarly, viral vectors containing wild-type p53 have been shown to negate the effects of tumor growth driven via p53 mutation. Extensive experimental evidence exists showing the inhibition or retarding of the cancer process by chemopreventive chemicals. These studies have been performed in animal models and cell systems. Although the human results of chemoprevention interventions are less convincing than the experimental models, considerable epidemiological evidence demonstrates an inverse relationship of some nutrient factors with cancer risks.

ASSESSING CARCINOGENICITY OF CHEMICALS

A number of in vivo and in vitro experimental systems are available to assess the potential carcinogenicity of chemicals. The types of tests available to identify chemicals with carcinogenic potential can be classified into general categories, based on the duration required to conduct the test (Table 8-21). Short-term tests are typically of the duration of days to a few weeks, intermediate-term tests last from weeks up to a year, whereas chronic long-term tests usually encompass 6 months to 2 years exposure to a chemical. These bioassays use bacterial and mammalian targets.

Short-Term Tests for Mutagenicity

Short-term tests for mutagenicity were developed to identify potentially carcinogenic chemicals based on their ability to induce mutations in DNA either in vivo or in vitro. A variety of in vivo and in vitro short-term tests are available to test the potential carcinogenicity of a chemical (Table 8-22). The majority of these tests quantify the mutagenicity of chemicals as a surrogate for carcinogenicity. Therefore, although they are usually very predictive of indirect acting and direct acting (if a metabolic source is provided), these tests routinely fail to detect non-genotoxic carcinogens.

Table 8-21

General Methods for Identification of Potential Carcinogens

METHOD	TIME FRAME
Short term	
Transformation in cell culture	Several weeks
Transformation in cell culture	1–3 months
Medium term	
Qualitative and quantitative analysis of preneoplasia	2–8 months
Long term	
Chronic bioassay in animals	18–24 months

In Vitro Gene Mutation Assays The most widely used short-term test is the Ames assay (Ames et al., 1975; Mortelmans and Zeiger, 2000). The relative simplicity and low cost of the test make it a valuable screening tool for mutagenic carcinogens. *Salmonella typhimurium* strains, deficient in DNA repair and unable to synthesize histidine, are used. In the presence of a mutagenic chemical, the defective histidine gene can be mutated back to a functional state (*back mutation*), resulting in a restoration of bacterial growth in medium lacking histidine. The mutant colonies, which can make histidine, are referred to as "revertants." The Ames test in basic form can detect direct but not indirect genotoxic carcinogens. With the inclusion of a metabolic source, specifically the 9000 g supernatant (S9) of a rat liver homogenate to promote metabolic conversion of the chemical, the Ames test can also detect indirect-acting genotoxic carcinogens. Fig. 8-29 describes the standard method used for performing the Ames assay.

Genetically unique strains of the *S. typhimurium* bacterium have been developed for determining specific mutational targets. Strains TA100 and TA1535 are able to detect point mutations whereas strains TA98, TA1537, and TA1538 are able to detect frame shift mutations. Chemicals are typically tested at several concentrations (usually five or more) and the mutation frequency (number of revertants) is calculated. Activation-independent (e.g., sodium azide, methyl methanesulfonate) and activation-dependent (e.g., 2-aminoanthracene) positive controls are included in each assay.

The mouse lymphoma assay is a mutagenicity assay used to determine whether a chemical is capable of inducing mutation in eukaryotic cells. Typically, mouse lymphoma L5178Y cells are used, and the ability of the cell cultures to acquire resistance to trifluorothymidine (the result of forward mutation at the thymidine kinase [TK] locus) is quantified. Another mammalian cell mutation assay, the Chinese hamster ovary (CHO) test, is also commonly used to assess the potential mutagenicity of chemicals. This assay uses the hypoxanthine–guanine phosphoribosyltransferase (HGPRT) gene as the endpoint. The basis for these assays is shown in Fig. 8-30. Cells are treated with the test chemical and then placed into suspension with selective medium for replication and fixation of induced mutations. Cells are then plated for colony growth, and after several days, colony numbers and colony size are recorded. The number of mutant colonies is a measure of the ability of the test chemical to induce a genetic change at the TK or HGPRT loci in these transformed cells.

As with the Ames assay, these assays are frequently performed in the presence of an exogenous metabolic source (e.g., irradiated epithelial cell feeder layer). Because not all carcinogens are mutagens and/or directly damage DNA, the concordance with the chronic in vivo bioassay for these mutagenicity assays is relatively low. For a historical perspective on the utilization of the Ames/Salmonella assay, a recent review by Claxton et al. (2010) provides more information on the use of the assay and the role of metabolic activation and mutagenicity testing with respect to genotoxic carcinogens.

In Vivo Gene Mutation Assays For the assessment of the carcinogenic potential of chemicals in vivo genotoxicity tests are important complement to in vitro mutagenicity tests. The in vivo tests have advantages over the in vitro test systems in that they

take into account whole animal processes such as absorption, tissue distribution, metabolism, and excretion of chemicals and their metabolites. The commonly used in vivo models include transgenic rodent mutation assay systems based on the genes of the *lac* operon, MutaMouse (Gossen et al., 1989), Big Blue (Kohler et al., 1991a, 1991b), and the recently developed Pig-a gene mutation assay (Gollapudi et al., 2015). Some details of the *lac* operon are shown in Fig. 8-31).

The MutaMouse is a transgenic mouse in which a vector prepared from bacteriophage λDNA (λgt10) has been stably inserted into the genome and exists within every cell. Within the λDNA sequence, the bacterial gene *lacZ*, which encodes for β-galactosidase, was inserted at the single *Eco*RI restriction site. The entire vector contains ~47,000 bp, of which the *lacZ* gene comprises 3126 bp. The construction and analysis of MutaMouse have been previously described (Gossen et al., 1989). The Big Blue transgenic mouse was developed using a 47.6-kb λshuttle vector containing the bacterial *lacI* gene (1080 bp), which encodes the repressor protein of the *lacZ* gene. As with the MutaMouse, this vector is stably inserted into the genome and exists in every cell. Details on the Big Blue system are described elsewhere (Kohler et al., 1991a, 1991b).

To detect mutations, following exposure of mice to test chemicals, mutations are analyzed in high molecular DNA isolated from the tissue under investigation. The next step is to isolate a viable λphage for the analysis of mutations in the *lacZ* or *lacI* genes from the mouse. The infectious λparticles are detected as plaques that form on a bacterial (*Escherichia coli* strain) lawn grown on an agar surface. In the case of MutaMouse a positive selection system is used that involves the scoring of clear plaques on titration plates to determine the total number of plaque forming units and on selection plates to determine the number of mutants (Gossen and Vijg, 1993). For Big Blue, a nonselectable color screening assay is used, scoring blue mutant plaques among the nonmutant clear plaques

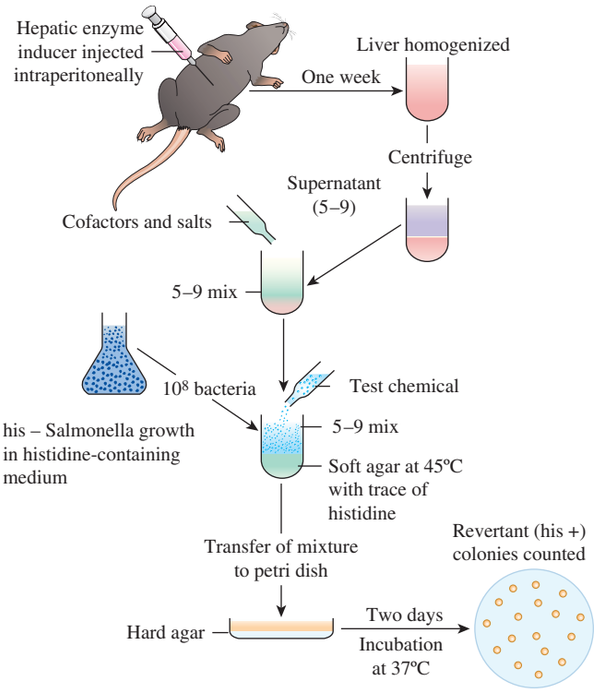

Figure 8-29. *Scheme of the Ames test for mutagenesis of chemicals in Salmonella bacterial strains.*

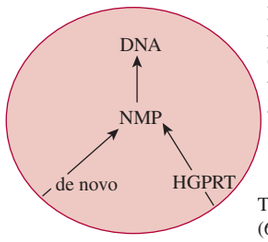
(Kohler et al., 1991a). In each case the ratio of mutants to the total population provides a mutation frequency for each chemical and each organ tested. As with the other short-term tests that have been discussed, it is unlikely that in vivo genotoxicity test systems will identify non-genotoxic/non–DNA-reactive compounds.

The Pig-a gene mutation assay is a relative new in vivo assay primarily performed in rats, based on the X-linked Pig-a gene (phosphatidylinositol *N*-acetylglucosaminyltransferase, subunit A), which is involved in the production of glycosylphosphatidylinositol (GPI) anchor proteins on the cell surface (Kinoshita et al., 1997). Loss of GPI anchored surface markers can be used as a surrogate for Pig-a gene mutation. The use of Pig-a as a positive in vivo somatic mutation reporter gene was initially proposed based on the studies of patients with paroxysmal nocturnal hemoglobinuria (Takahashi et al., 1993; Takeda et al., 1993; Boccuni et al., 2000). Assays of Pig-a gene mutation in vivo were developed thereafter in rodents and have undergone intensive international validation (Miura et al., 2008a, 2008b; Dertinger et al., 2011; Kimoto et al., 2016). Currently, the assay is optimized for measuring the Pig-a mutant phenotype in peripheral blood erythrocytes including reticulocytes (RETs) and red blood cells (RBC) or rats primarily by quantification of CD59-negative RETs and RBCs (the RET^{CD59-} and RBC^{CD59-} respectively) (Fig. 8-32). The typical recommended study design is 28-day repeated dose subchronic toxicity study in male rats consisting of five to six doses (including a concurrent vehicle control), with blood sample collected at the end of treatment and analyzed (at least 1 to 5 million erythrocytes)

Mammallian cell line used for gene mutation studies

Mouse lymphoma L5178Y	TK, HGPRT
CHO	HGPRT
V79 hamster cells	HGPRT

Selection of forward mutations by loss of HPGRT + phenotype in V79 or Chinese hamster ovary cells.



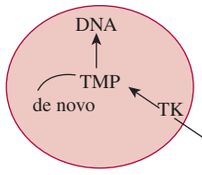
Hypoxanthine-guanine phosphoribosyltransferase (HGPRT) is an X-linked gene that confers resistance to purine analogues such as 6-thioguanine.

Toxic analogue (6-thioguanine)

Performed in the presence of an activation system or hepatic feeder layer

Selection of mutagen-induced TK –/– phenotype in TK +/– in mouse lymphoma assay (MOLY) in L5178Y cells. This assay detects forward mutations at the TK locus.

Treat TK (+/–) cells with test compound. Fluoruracil is converted to a toxin, killing the cells. If mutation in TK occurs, FU is not metabolized to a toxin and colonies grow.



Thymidine kinase (TK) confers resistance to pyrimidine analogues. It is a somatic gene.

Toxic analogue (bromodeoxyuridine)

with flow cytometer (Gollapudi et al., 2015). The Pig-a gene is highly conserved in humans, rats, mice, and monkeys, therefore it allows comparison of mutation induction across multiple species. In addition, it can be easily integrated into standard toxicity studies as well as existing genotoxicity endpoints such as chromosome aberrations, micronucleus, and DNA damage (comet) assays (Stankowski et al., 2011, 2015) to provide additional data for toxicity assessment.

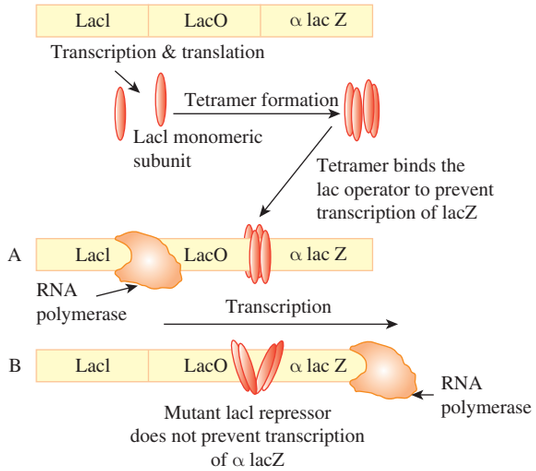

Figure 8-31. *Schematic representation of the lac operon in E. coli.*

Chromosomal Alterations Chromosomal alterations are quite common in malignant neoplasms, as such the detection of chromosomal abnormalities by test chemicals is considered an excellent test for the assessment of carcinogenic potential. Both in vivo and in vitro assays are available to assess chromosomal alterations. In mammalian cell lines, most of the test systems used the same lines as used in the mutation assay. To assess induction of chromosomal alterations, cells are harvested in their first mitotic division after the initiation of chemical exposure. Cells are stained with Giemsa, and scored for completeness of karyotype (21 ± 2 chromosomes). The classes of aberrations recorded include breaks and terminal deletions, rearrangements and translocations, as well as despiralized chromosomes, and cells containing 10 or more aberrations.

Sister chromatid exchanges (SCEs) are a measure of DNA damage and increased levels of DNA damage, events that are associated with mutation induction and cancer. During metaphase, sister chromatids, each encompassing a complete copy of one chromosome, are bound together through specific protein interactions. SCEs are a reflection of an interchange of DNA between different chromatids at homologous loci within a replicating chromosome (Latt et al., 1981). Differential staining of chromatids is therefore used to assess SCEs. Typically, 5-bromodeoxyuridine (BrdU) is

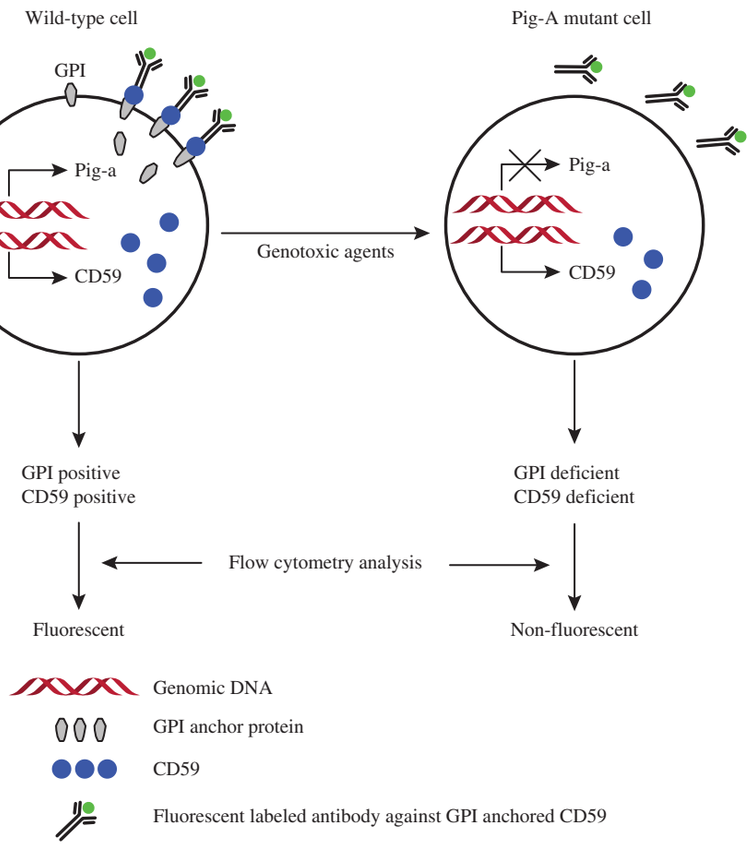

Figure 8-32. *Principle of the rat erythrocyte Pig-a assay.*

added along with the test chemical for one cell replication followed by replacement of the medium with medium containing BrdU and colcemid, without test chemical. Cells are then harvested, stained and second-division metaphase cells scored to determine the frequency of SCE/cell for each dose level.

In vivo analysis of chromosomal alterations has been described since the 1980s (Sasaki, 1980). Disruption of the DNA replication process or damage to chromosomes by chemicals can alter the genetic material distributed to either of the two daughter nuclei. When this occurs, the genetic material that is not incorporated into a new nucleus may form its own "micronucleus," which is clearly visible with a microscope. For this assay, animals are exposed to chemicals and the frequency of micronucleated cells is determined at some specified time after treatment. Micronucleus tests must be performed on cells that are dividing, most typically in cells from bone marrow samples (Heddle et al., 1983). As with other short-term tests, the micronucleus test provides complementary information to gene mutation data but neither test enhances the ability to detect genotoxic carcinogens, nor is capable of detecting non–DNA-reactive carcinogens. However, this assay does provide information on the ability of a chemical to disrupt mammalian chromosome structure and function.

DNA Damage Primary DNA damage represents possible premutational events that can be detected, either directly or indirectly, by a number of techniques using mammalian cells in culture or using rodent tissue. Unscheduled DNA synthesis (UDS) is a commonly used assay that measures the ability of a test article to induce DNA lesions by quantifying the increase in DNA repair. Among the available techniques is the measurement of DNA strand breaks both in vivo and in vitro including the gamma gamma-H2AX assay (Miyamae et al., 1997; Kuo and Yang, 2008). Although a wide array of assays are available to assess DNA damage, the comet assay, or single cell gel electrophoresis, has become one of the standard methods for assessing DNA damage and repair at the individual cell level. Since its introduction in 1988, the alkaline comet assay has been modified to increase the utility of this technique for detecting various forms of DNA damage (e.g., single- and double-strand breaks, oxidative DNA base damage, and DNA–DNA/DNA–protein/DNA–Drug cross-linking) and DNA repair in virtually any eukaryotic cell (Singh et al., 1988). Through the use of lesion-specific endonucleases, the levels of UV-induced pyrimidine dimers, oxidized bases, and alkylation damage can be assessed in biological samples (Miyamae et al., 1997, 1998; Collins, 2004; Pu et al., 2015). The in vivo version of the comet assay has recently been implemented in regulatory genotoxicity testing of pharmaceuticals and chemicals with inclusion into the ICH S2R21 guidance (EMA, 2008) and adoption in the Organization for Economic Co-operation and Development (OECD) Test Guideline (TG) 489 (OECD, 2014).

Short-Term Tests: Transformation Assays A variety of in vitro test methods including cell transformation assays have been developed to assess the carcinogenic potential of chemicals (Creton et al., 2012). The C3H/10T½ cell line has been widely used for the transformation assay. It was originally derived from fibroblasts taken from the prostate of a C3H mouse embryo. The cells are approximately tetraploid but the chromosome number in the cells varies widely. As such, these cells are chromosomally abnormal and have already passed through some of the stages that might be involved in the production of a cancerous cell. Upon plating these cells, they will stop growing when their density is sufficiently high (contact growth inhibition). However, the contact inhibition can fail, resulting in cell piling forming a transformed colony. Therefore, following exposure to xenobiotics, this assay assesses carcinogenic potential based on the percentage of colonies that are transformed (Reznikoff et al., 1973).

The most frequently used endpoint for cell transformation is morphological transformation of mammalian cell fibroblasts in culture. Transformation assays using BALB3T3 and Syrian hamster embryo (SHE) cells are available for the assessment of the carcinogenic potential of chemicals. BALB/3T3 transformation assay, however, has not gained full acceptance as a carcinogenic screening assay mainly due to issues regarding its relatively low sensitivity, low reproducibility, and relatively long test period (Schechtman, 1985; Sakai and Sato, 1989). The SHE cell assay, a diploid cell transformation assay, measures carcinogenic potential of xenobiotics by assessing transformed colonies based on morphological criterion. The SHE cell assay has several features that make it an appealing method to evaluate the carcinogenic potential of xenobiotics: (1) the assay has a >85% concordance with the two-year rodent bioassay; (2) the stages involved in the clonal transformation of SHE cells (e.g., morphological transformation, immortalization, and tumorigenicity) closely resemble those associated with the classic defined stages of carcinogenesis (e.g., initiation, promotion, and progression); and (3) non-genotoxic/non–DNA-reactive carcinogens elicit a positive response on morphological transformation in the SHE cell assay (Barrett and Lamb, 1985; LeBoeuf et al., 1990; Isfort et al., 1994, 1996). The SHE assay offers an alternative, regulatory approved, means to check the validity of the positive result before embarking on potentially unnecessary and expensive chronic or subchronic testing protocols.

Chronic Testing for Carcinogenicity

The majority of in vivo carcinogenicity testing is performed in rodent models. The administration of chemicals in the diet, often for extended periods, for assessment of their safety and/or toxicity began in the 1930s (Sasaki and Yoshida, 1935). Animal testing today remains a standard approach for determining the potential carcinogenic activity of xenobiotics. In addition to the lifetime exposure rodent models, organ-specific model systems, multistage models, and transgenic models are being developed and used in carcinogen testing (Table 8-23).

Chronic (Two Year) Bioassay Two-year studies in laboratory rodents remain the primary method by which chemicals or physical agents are identified as having the potential to be hazardous to humans. The most common rodents used are the rat and mouse. Typically the bioassays are conducted over the lifespan of the rodents (two years). Historically, selective rodent strains have been used in the chronic bioassay; however, each strain has both advantages and disadvantages. For example, the NTP typically uses Fisher 344 (F344) rats and B6C3F1 mice. The F344 rat has a high incidence of testicular tumors and leukemias whereas the B6C3F1 mouse is associated with a high background of liver tumors (Table 8-24).

In the chronic bioassay, two or three dose levels of a test chemical and a vehicle control are administered to 50 males and 50 females (mice and rats), beginning at 8 weeks of age, continuing throughout their lifespan. The route of administration can be via oral (gavage), dietary (mixed in feed), or inhalation (via inhalation chambers) exposure. Typically a number of short-term in vivo tests are conducted prior to the chronic bioassay to determine

acute toxicity profiles, appropriate route of administration, and the maximum tolerated dose (MTD). MTD is defined for regulatory purposes as the highest daily dose of a chemical that does not cause overt toxicity in a 90-day study in laboratory mice or rats. Generally, the MTD is used to set the high dose in the chronic study. The use of the MTD as the upper dose level has been questioned by many investigators, as it is recognized that the doses selected represent those that are considered unrealistically high for human exposure. Pharmacokinetics and metabolism at high dose are frequently unrepresentative of those at lower doses; in addition, a general relationship between toxicity and carcinogenicity cannot be drawn for all classes of chemicals. During the study, food consumption and bodyweight gain should be monitored and the animals observed clinically on a regular basis; at necropsy, the tumor number, location, and diagnosis for each animal is thoroughly assessed.

Organ-Specific Bioassays and Multistage Animal Models Many tissue-specific bioassays have been developed with the underlying goal being to produce a sensitive and reliable assay that could be conducted in a time frame shorter in duration than the two-year chronic bioassay. These assays are commonly used to detect carcinogenic activity of chemicals in various target organs (Weisburger and Williams, 1984). Of the many models available, three models, the liver, skin, and lung models are more widely used.

Carcinogenicity Testing in the Liver The liver represents a major target organ for chemical carcinogens. It has been estimated that nearly half of the chemicals tested in the two-year chronic bioassay by the NTP showed an increased incidence of liver cancer. The rodent liver has been used as an animal model for carcinogenesis since the 1930s. Early pioneering work by Peraino and Pitot as well as Farber showed the multistaged process that occurs in the liver. The multistage nature of carcinogenesis is paralleled in the animal models; the system is characterized by well-defined changes including the formation of initiated cells by genotoxic chemicals that then progress to preneoplastic focal lesions, which subsequently convert into neoplasms. The use of preneoplastic lesions as endpoints in carcinogenicity testing may shorten experiment from two years to a few

months. Several rodent liver focus assays have been developed to assess the ability of a chemical to induce liver cancer and study the mechanisms involved in tumor development (Williams, 1982; Bannasch, 1986a, 1986b). Liver carcinogenesis assays have been developed to study and distinguish chemicals that affect the initiation or promotion stage of hepatocarcinogenesis. During the assay for initiating activity of a chemical, the test substance is given prior to exposure to a promoting chemical. Although a single initiating dose can result in the induction of focal lesions, exposure over a several week period is often used to increase the sensitivity of the model (Williams, 1982; Parnell et al., 1988). Phenobarbital is a commonly used tumor promoter; however, a wide range of chemicals have also been used as promoting agents (Solt and Farber, 1976; Oesterle and Deml, 1988). To assess the promoting activity of a chemical, the liver is initiated with a genotoxic chemical, often diethylnitrosamine. The test chemical is then administered for a duration of weeks to several months, and chemicals with promoting activity may stimulate the proliferation of initiated cells or may inhibit the proliferation of the surrounding putatively normal cells. The dose of the initiating carcinogen should represent a dose that will not induce liver tumors during the course of the experiment.

Another approach was developed in Japan by Ito and co-workers (Ogiso et al., 1990; Ito et al., 1994; Shirai et al., 1999). The "Ito assay" requires 8 weeks to perform. Rats are initiated with a single dose of diethylnitrosamine, followed by a 2-week recovery period, after which the rats are exposed to the test compound for 8 weeks. After 1 week of exposure to the test substance, the animals are given a two-third partial hepatectomy. The control group receives the same initiation and partial hepatectomy, but is not exposed to the test chemical. Hepatic focal lesions, while individually are clonal in nature, express a number of phenotypic alterations in various enzyme markers. The endpoint used in the Ito assay is the formation of liver lesions that stain for GST-P, a marker that stains many focal lesions in the rat. Using this assay, these investigators demonstrated a significant correlation between the results obtained using this assay and medium- and long-term study results (Ogiso et al., 1990). This group has also modified the original procedure to enable the detection of promoting chemicals. In this protocol, carcinogens are given over a 4-week period to initiate the formation of focal lesions, after which, test chemicals are administered for an additional 24- to 36-week period (Ito et al., 1997). In this manner, the ability of the test chemical to promote the growth of preneoplastic lesions can be assessed. The newborn mouse model originally described by Shubik and co-workers (Pietra et al., 1959) has also been used as a model for hepatocarcinogenesis (Vesselinovitch et al., 1985; Fujii, 1991). In this model, a single dose of diethylnitrosamine is administered to infant mice to initiate focal lesions. This step is then followed by exposure to test chemicals for several weeks to assess their potential to promote focal lesion development in the liver (Weghorst and Klaunig, 1989; Weghorst et al., 1989; Klaunig et al., 1990)

Identification of hepatic foci in H&E-stained sections is regarded as the most reliable approach for the diagnosis and quantification of preneoplastic liver lesions in rodents. Preneoplastic lesions are obligatory precursor lesions that can lead to liver tumors and will progress to benign and malignant liver cell tumors without further chemical exposure, and are used as endpoints in carcinogenicity testing (Pitot et al., 1987; Pereira and Herren-Freund, 1988; Ito et al., 1989; Maronpot et al., 1989). In addition to the sensitive detection of these preneoplastic lesions in conventional H&E staining, a number of histochemically detectable phenotypic alterations have been used for their quantification; however, these markers are only useful in the rat model, as focal lesions in mice do not exhibit these same phenotypic markers (Klaunig, 1993; Kolaja et al., 1995, 1996a, 1996b).

Carcinogenicity Testing in the Skin The mouse skin model is one of the most extensively studied and used models for understanding multistage carcinogenesis. This model of carcinogenesis is an assay that has been used to dissect mechanisms of carcinogenesis and is also purported to be a useful intermediate-term cancer bioassay. The skin was the target organ of the first experimental induction of chemical carcinogenesis (Yamagiwa and Ichikawa, 1915). The early studies by Friedwald and Rous (1944) and Berenblub and Shubik (1947) introduced the two-stage concept of carcinogenesis in the skin (Fig. 8-33). This model exploits many of the unique properties of mouse skin, one major being that the development of neoplasia can be followed visually. In addition, the number and relative size of papillomas and carcinomas can be quantified as the tumors progress.

Both initiating and promoting activities of chemical carcinogens can be assessed using this model. In the promotion assay, a number of chemical carcinogens have been used to initiate cells in mouse skin, including urethane, UV light, benzo(*a*)pyrene, and dimethylbenzanthracene, with the latter being of more common usage. The requirement for all initiating chemicals is to induce a genotoxic event that upon failure to repair DNA damage results in the formation of a mutated cell. Grossly, initiated cells of the skin appear identical to normal skin. Initiation in skin is frequently linked with the mutation of the *CHr* gene. Because the terminally differentiated cells in the skin are no longer capable of undergoing cell division, only initiated cells retain their proliferative capacity and thus represent the cell populations that give rise to tumors. To assess promotion by a chemical, an initiating chemical is applied first and is followed by the administration of a test substance for several weeks on the shaved skin of mice (Slaga, 1984). The promotion of initiated keratinocytes is commonly assessed using the phorbol ester 12-*O*-tetradecanoylphorbol-13-acetate (TPA), which is routinely included as a positive control in this assay. The current hypothesis is that during the initiation stage the expansion or of initiated cells occurs as a result of inflammation and hyperplasia from either TPA or through mechanical wound healing mechanisms. Upon repeated application of tumor promoters, selective

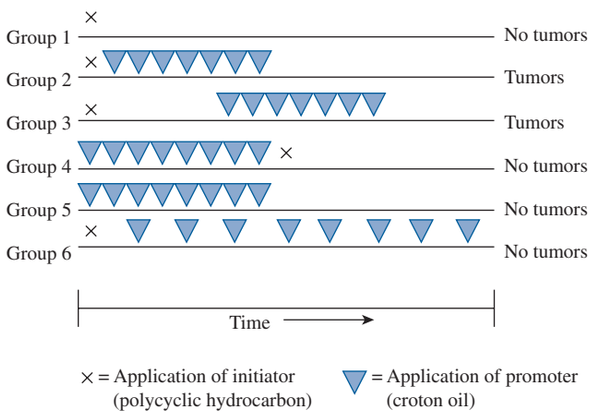

Figure 8-33. *Experiments demonstrating the initiation and promotion phases of carcinogenesis in mice. Group 2: application of promoter repeated at twice-weekly intervals for several months. Group 3: application of promoter delayed for several months and then applied twice weekly. Group 6: promoter applied at monthly intervals.*

clonal expansion of initiated keratinocytes occurs, resulting in skin papillomas, which over time can progress to carcinomas. In the standard two-stage protocol for mouse skin, malignant progression is relatively rare with approximately 5% of the papillomas progressing to the carcinoma stage. For the detection of initiating activity, the test substance is applied to skin prior to promotion with phorbol esters. Several mouse models are available, including hairless mice and SENCAR mice, both of which have enhanced sensitivity to the induction of skin cancer (Brown and Balmain, 1995; Sundberg et al., 1997).

Carcinogenicity Testing in the Lung Strain A mice are genetically susceptible to the development of lung tumors, with lung tumors being observed in control animals as early as 3 to 4 weeks of age with a steady increase to nearly 100% by 24 months of age (Shimkin and Stoner, 1975). Chemically induced tumors appear to be derived from hyperplastic lesions that progress to adenoma, carcinoma within adenoma, and ultimately to carcinomas (Stoner et al., 1993). In this model, carcinogenicity is typically assessed as an acceleration of tumor development rather than an increase in tumor incidence. The protocol currently used is that the chemical is administered for a period of 8 weeks, after which the animals remain on test for 4 additional months without chemical exposure. The strain A mouse lung tumor assay is sensitive to particular classes of chemicals, such as PAHs, nitrosamines, nitrosoureas, carbamates, aflatoxin, certain metals, and hydrazines (Stoner and Shimkin, 1985; Maronpot et al., 1986; Stoner, 1991).

Carcinogenicity Testing in Other Organs Test systems to examine the ability of a chemical to promote neoplastic development at organ sites other than liver, skin, and lung have also been developed. The available systems include animal models directed at examining carcinogenicity in the kidney, bladder, pancreas, stomach, colon, small intestine, and oral cavity. These models vary in the initiating carcinogen used, and frequency, duration, and site of application, as well as duration of promoting chemical exposure. Table 8-25 provides an overview of the animal models available for these target organs.

Transgenic Animals in Carcinogenicity Assessment

Due to the development of animal models with genetic alterations that invoke a susceptibility to carcinogenesis by chemicals, the use of transgenic and knockout animals in carcinogenicity assessment is gaining more popularity. The common models that have been used include the Tg.AC and rasH2 transgenic mice, and $p53^{+/-}$ and $XPA^{-/-}$ knockout mice (Gulezian et al., 2000; Pritchard et al., 2003; Boverhof, 2011; Eastmond et al., 2013). The feasibility of using transgenic animal models as an alternative to the two year chronic bioassay was evaluated in a review by the Health and Environmental Sciences Institute (HESI) branch of the International Life Sciences Institute (ILSI). In this assessment, 21 chemicals were evaluated, encompassing genotoxic, nongenotoxic, and noncarcinogenic chemicals. The conclusions drawn from the scientific review suggested that these models appear to have usefulness as screening models for assessment of chemical carcinogenicity; however, they do not provide definitive proof of potential human carcinogenicity. Further the scientific panel suggested that these models could be used in place of the mouse two-year bioassay (Blaauboer et al., 1998; Cohen et al., 2001). Coupled with information on genotoxicity, particularly DNA reactivity, structure–activity relationships, results from other bioassays, and the results of other mechanistic investigations including toxicokinetics, metabolism, and mechanistic information, these alternate mouse models for carcinogenicity appear to be useful models for assessing the carcinogenicity of chemicals. In general, replacement of the two-year rodent bioassay by transgenic mouse assay has not been as successful as with anticipated (Boverhof, 2011). However, as models for studying the roles of specific pathways and mechanisms in the carcinogenesis process, these models remain an excellent resource.

New Approaches A major concern for the correct evaluation of the safety of chemicals is the need to obtain reliable and pertinent scientific information on which to develop proper risk evaluation and assessment. Our current bioassays approaches have been criticized as being too time consuming and not pertinent to human health. Research during the last decade of the 20th century and the turn of the 21st century have resulted in a dramatic increase in our knowledge of the cellular and molecular pathways that contribute to the induction and prevention of cancer. This coupled with technological advances in high-throughput assays, and computational science has raised the question if the current approaches for carcinogenesis evaluation of chemicals (and mixtures) should be reevaluated. Following a NRC report in 2007 (Toxicity Testing in the 21st Century: A Vision and a Strategy), several approaches have begun utilizing high-throughput and computational approaches to evaluate the effects of chemicals on biological processes and pathways that are important in toxicity (including cancer). These approaches are directed to using cells, cell lines and components of cells, as well as in silico computer models. Significant progress has been made on several of these recently launched approaches including the USEPA Toxcast program, the NTP/NIEHS lead Tox 21 program (tox21 is a consortium of NIH, FDA, USEPA), the NIH-NCATS-FDA-sponsored microphysiological systems, and the EU sponsored SEURAT-1 (Knudsen et al., 2015). In particular, the last decade has witnessed a dynamic growth in the development of in silico methods and their application in predicting chemical toxicity including genotoxicity and carcinogenesis (examples can be found in Benfenati et al., 2009; Golbamaki and Benfenati, 2016; Raies and Bajic, 2016; and Frenzel et al., 2017).

CHEMICAL CARCINOGENESIS IN HUMANS

Recently, the IARC (Vol 100A-F) has reported a review of chemically induced cancer in humans. This body has identified and classified 120 agents as carcinogenic in humans. This review is divided into six major categories of carcinogens deemed to be human carcinogens by the IARC. These include pharmaceuticals; biological agents; metals, particles, and fibers; radiation; personal habits and household exposures; and chemical agents and related occupations. A number of factors have been implicated in the induction of cancer in humans. Infectious agents, lifestyle, medical treatments, environmental, and occupational exposure account either directly or indirectly to the majority of cancers seen in humans. Of these, the component that contributes the most to human cancer induction and progression is lifestyle: tobacco use, alcohol use, and poor diet (Table 8-26). Tobacco usage either through smoking tobacco, chewing tobacco, or tobacco snuff-type products is estimated be responsible for 25% to 40% of all human cancers. In particular, a strong correlation between tobacco usage and mouth, larynx, lung, esophageal, and bladder cancer exists. It has been estimated (Doll and Peto, 1981) that 85% to 90% of

Target Organ Models for Studying Chemically Induced Carcinogenesis

ORGAN	SPECIES	INITIATING CARCINOGEN	INITIATOR DURATION	CARCINOGEN (PROMOTER) DURATION	REFERENCES
Kidney	Rat	*N*-Ethyl-*N*-hydroxyethylnitrosamine	Single exposure	20 weeks	Hiasa et al. (1991)
Bladder	Rat	*N*-Nitrosobutyl (4-hydroxybutyl)amine	4 weeks	32 weeks	Fukushima et al. (1983)
Pancreas	Rat, Syrian hamsters	*N*-nitrosobis(2-oxopropyl) amine, *N*-nitroso (2-hydroxypropyl) (2-oxopropyl)amine	Single exposure		Longnecker et al. (1984, 1985)
Stomach (forestomach)	Rat	Benzo(*a*)pyrene	1–2 times/week, 4 weeks	40 weeks	Silva et al. (1995)
Stomach (glandular)	Rat	*N*-Methyl-*N*′-nitro-*N*-nitronitrosoguanidine	Single exposure	40 weeks	Takahashi et al. (1986)
Colon	Rat	Azoxymethane	2 exposures	12 weeks	Yamashita et al. (1995)
Small intestine	Rat, mice	1,2-Dimethylhydrazine *N*-Ethyl-*N*′-nitro-*N*-nitrosoguanidine	2–9 weeks 4 weeks	16–20 weeks	Lindenschmidt et al. (1987), Jagadeesan et al. (1994)
Oral cavity (lip, oral, nasal)	Rat	4-Nitroquinoline *N*-oxide	4 weeks		Johansson et al. (1989)
Oral cavity (tongue)	Rat	4-Nitroquinoline *N*-oxide	8 weeks		Tanaka et al. (1998)
Buccal cells (squamous cell carcinoma)	Syrian hamster	—	—	Repeated application 10–16 weeks	Solt et al. (1987)
Buccal cells (squamous cell carcinoma)	Syrian hamster	Dimethylbenz[*a*]anthracene	Single exposure	45 weeks	Gimenez-Conti and Slaga (1993)

Table 8-26

Carcinogenic Factors Associated with Lifestyle

CHEMICAL(S)	NEOPLASM(S)
Alcohol beverage	Esophagus, liver, oropharynx, and larynx
Aflatoxins	Liver
Betel chewing	Mouth
Dietary intake (fat, protein, calories)	Breast, colon, endometrium, gallbladder
Tobacco smoking	Mouth, pharynx, larynx, lung, esophagus, bladder

all lung cancer cases in the United States are a direct result of tobacco use. The induction of pancreatic cancer also appears to have a linkage to tobacco use. Alcohol consumption also contributes anywhere from 2% to 4% of cancers of the esophagus, liver, and larynx.

Poor diets whether high-fat, low-protein, high-calories or diets lacking in needed antioxidants and minerals account for anywhere from 10% to 70% of human cancers. Diet contaminated by molds such as *Aspergillus flavis* (which produces aflatoxin B1) have been linked epidemiologically to a higher incidence of liver cancer. It also appears that aflatoxin B1 exposure coupled with hepatitis B virus infection produces an increased incidence of liver cancer compared to aflatoxin B1 or hepatitis B exposure individually. Mold-contaminated foodstuffs have also been shown to produce nitroso compounds.

There is substantial evidence that overnutrition either through excess calories and/or high-fat diets contribute to a number of human cancers (Doll and Peto, 1981). In particular, high-fat and high-calorie diets have been linked to breast, colon, and gall bladder and liver cancer in humans. Diets poor in antioxidants and/or vitamins such as vitamin A and vitamin E probably also contribute to the onset of cancer. The method of cooking may also influence the production of carcinogens produced in the cooking process. Carcinogenic heterocyclic amines (HCAs) and PAHs are formed during broiling and grilling of meat. Acrylamide, a suspected human carcinogen, has been found in fried foods at low concentrations.

Table 8-27

Occupational Human Carcinogens

AGENT	INDUSTRIAL PROCESS	NEOPLASMS
Asbestos	Construction, asbestos mining	Peritoneum, bronchus
Arsenic	Mining and smelting	Skin, bronchus, liver
Alkylating agents (mechlorethamine hydrochloride and bis[chloromethyl] ether)	Chemical manufacturing	Bronchus
Benzene	Chemical manufacturing	Bone marrow
Benzidine, β-naphthylamine	Dye and textile	Urinary bladder
Chromium and chromates	Tanning, pigment making	Nasal sinus, bronchus
Nickel	Nickel refining	Nasal sinus, bronchus
Polynuclear aromatic hydrocarbons	Steel making, roofing, chimney cleaning	Skin, scrotum, bronchus
Vinyl chloride monomer	Chemical manufacturing	Liver
Wood dust	Cabinet making	Nasal sinus
Beryllium	Aircraft manufacturing, electronics	Bronchus
Cadmium	Smelting	Bronchus
Ethylene oxide	Production of hospital supplies	Bone marrow
Formaldehyde	Plastic, textile, and chemical	Nasal sinus, bronchus
Polychlorinated biphenyls	Electrical-equipment production and maintenance	Liver

A number of occupations have been associated with the development of specific cancers (Table 8-27). As noted earlier, the linkage between chimney sweeps who as young boys in England were exposed to PAHs through the constant exposure to soot developed scrotal cancer. The linkage between occupational exposure to asbestos and the development of bronchiogenic carcinoma and as well as malignant mesothelioma has been clearly established. The appearance of bronchiogenic carcinoma was much higher in shipyard workers who were exposed to both asbestos and cigarette smoking. Muscat and Wynder (1995) noted no association between cigarette smoking and mesothelioma formation. Similarly, asbestos exposure by itself (without smoking) does not seem to increase the risk of bronchiogenic carcinoma. Aromatic amines used in the chemical and dye industries have been shown to produce or induce bladder cancer in humans. Prolonged high exposure to benzene in an occupational setting has been linked to the formation of acute myelogenous leukemia in humans.

Table 8-28

Human Carcinogenic Chemicals Associated with Medical Therapy and Diagnosis

CHEMICAL OR DRUG	ASSOCIATED NEOPLASMS
Alkylating agents (cyclophosphamide, melphalan)	Bladder, leukemia
Azathioprine	Lymphoma, reticulum cell sarcoma, skin, Kaposi sarcoma
Chloramphenicol	Leukemia
Diethylstilbestrol	Vagina (clear cell carcinoma)
Estrogens	Liver cell adenoma, endometrium, skin
Phenacetin	Renal pelvis (carcinoma)
Phenytoin	Lymphoma, neuroblastoma
Thorotrast	Liver (angiosarcoma)

A number of drugs and medical diagnostic tools have also been linked to the induction of human cancer (Table 8-28). Anticancer drugs such as the alkylating agent cyclophosphamide have been associated with bladder tumors and leukemia in patients receiving these treatments. The administration of the synthetic estrogenic compound diethylstilbestrol to pregnant women in order to improve embryo implantation and prevent spontaneous abortion has been shown to result in the formation of clear cell carcinomas of the vagina in the female offspring of mothers treated with diethylstilbestrol during pregnancy. The use of oral contraceptives containing synthetic estrogens as their major or only component has been implicated in the induction of liver cell adenomas. In addition, an association exists between prolonged use of estrogenic oral contraceptives and an increase incidence of premenopausal breast cancer. Androgenic steroids and synthetic testosterone compounds have been implicated in hepatocellular carcinoma induction. Therapeutic immunosuppression given to transplant patients or arising secondary to selective diseases such as AIDS result in an increase in a variety of different neoplasms. These results further support the role of the immune system in identifying and removing early preneoplastic cells from the body. In addition, the previously used diagnostic tracer Thorotrast has been sufficiently linked to the formation of hemangiosarcomas.

EVALUATION OF CARCINOGENICITY IN HUMANS

The assessment and designation of a chemical or a mixture of chemicals as carcinogenic in humans is evaluated by various agencies worldwide. The evaluation usually encompasses epidemiological, experimental animal, and in vitro data utilizing assays as described earlier in this chapter. One of the first schemes for the classification of an agent's carcinogenicity was devised by the IARC (Table 8-29). The IARC approach assigns the chemical or mixture to one of five groupings based upon strength of evidence

Table 8-29

IARC Classification of the Evaluation of Carcinogenicity for Human Beings

GROUP	EVIDENCE
1. Agent is carcinogenic to humans	Human data strong Animal data strong
2A. Agent is probably carcinogenic to humans	Human epidemiology data suggestive Animal data positive
2B. Agent is possibly carcinogenic to humans	Human epidemiology data weak Animal data positive
3. Agent is not classifiable as to carcinogenicity to humans	Human and animal data inadequate
4. Agent is probably not carcinogenic to humans	Human and animal data negative

for the chemical's possible, probable, or definite carcinogenicity to humans. In Group 1 classification, the chemical or mixture is classified as definitely carcinogenic to humans. The second grouping is Group 2A in which the chemical is probably carcinogenic to humans. In Group 2B, the chemical is classified as possibly carcinogenic to humans. Group 3, the agent is not classifiable. And in the last group, Group 4, the agent is not carcinogenic to humans. The IARC produces a series of monographs that describe the methodology for the evaluation of specific chemicals and the rationale for their final classification. Currently, 120 chemicals or mixtures or exposure circumstances have been classified by IARC as falling in Group 1, which shows sufficient evidence for carcinogenicity to humans.

Similar classifications exist for the USEPA, the Food & Drug Administration, and the European Community (EC). The classification of chemicals with regard to human carcinogenicity can many times be very difficult in particular, when animal data and/or epidemiological data in humans are inconclusive or confounded.

New USEPA Guidelines for Cancer Risk Assessment (2005) uses descriptors for defining the relative carcinogenic risk to humans (Table 8-30). These descriptors include carcinogenic to humans, likely to be carcinogenic to humans, suggestive evidence of carcinogenic potential, inadequate information to assess carcinogenic potential, and not likely to be carcinogenic in humans. The EPA Guidelines take into account the understanding of the mode of carcinogenic action and associated key precursor events needed for the cancer to form (Table 8-31). Central to the USEPA Guidelines for Cancer Risk Assessment is the utilization of the mode of action framework to define the key events in rodents, and assessment of whether those same key events and mode of action can occur in humans (Table 8-32). This approach is similar to that has been developed by the International Program on Chemical Safety and by panels in the International Life Sciences Institute. Similar to the mode of action analysis, adverse outcome pathway (AOP) approach was recently launched by OECD, executed in collaboration with USEPA, Joint Research Center of European Commission, the US Army Corps of Engineers, to support chemical risk assessment based on mechanistic reasoning. An AOP is a conceptual framework that describes existing knowledge (in vitro data, animal toxicity studies, and in silico computational systems) concerning the linkage

Table 8-30

USEPA Cancer Guidelines Descriptors

Carcinogenic to humans:
– Strong evidence of human carcinogenicity, including convincing epidemiological evidence of a causal association between human exposure and cancer
– The mode(s) of carcinogenic action and associated key precursor events have been identified in animals, and there is strong evidence that the key precursor events in animals are anticipated to occur in humans

Likely to be carcinogenic to humans:
– Weight of the evidence is adequate to demonstrate carcinogenic potential to an agent in animal experiments in more than one species, sex, strain, site, or exposure route, with or without evidence of carcinogenicity in humans

Suggestive evidence of carcinogenic potential:
– The weight of evidence is suggestive of carcinogenicity; a concern for potential carcinogenic effects in humans is raised, but the data are judged not sufficient for a stronger conclusion

Inadequate information to assess carcinogenic potential:
– Available data are judged inadequate for applying one of the other descriptors

Not likely to be carcinogenic to humans:
– This descriptor is appropriate when the available data are considered robust, there is no basis for human hazard concern, evidence in both humans and animals that the agent is not carcinogenic

Table 8-31

USEPA Mode of Action Definitions

Mode of action: Key events and processes, starting with the interaction of an agent with a cell, through functional and anatomical changes, resulting in cancer or other health endpoints

Key event: Empirically observable precursor step that is itself a necessary element of the mode of action or is a biologically based marker for such an element

Table 8-32

USEPA Mode of Action Framework

Mode of action criteria
Summary description of the hypothesized mode of action
Identification of key events
Strength, consistency, specificity of association
Dose–response concordance
Temporal relationship
Biological plausibility and coherence
Consideration of the possibility of other MOAs
Is the mode of action sufficiently supported in the test animals?
Is the mode of action relevant to humans?
Which populations or life stages can be particularly susceptible to the mode of action?

between a chemical interacting with a biological process, a direct molecular initiating event (MIE), and an adverse human or environmental health outcome (AO), by capturing the sequential chain of causally linked key events (KEs) at different levels of biological organization (Fig. 8-34). KEs are both measurable and essential for the AO, and the evidence supporting the causal linkages between individual KEs, termed Key Event Relationships (KERs), should be based on both biological plausibility and empirical data. A number of AOPs have been developed or currently under development that can be found on AOP Wiki (http://aopwiki.org/) as well as the AOP Knowledge Base (http://aopkb.org/).

The current listing of chemicals, occupations, or behaviors deemed to be carcinogenic in humans by IARC and the NTP are noted in Tables 8-33 to 8-34, respectively.

SUMMARY

The induction of cancer by chemicals is well established in animal models as well as in humans. Linkages between chemicals found in human lifestyle, occupational exposure, and environmental exposure provides strong evidence for the induction or contribution to environmental occupational lifestyle carcinogens to human cancer. Cancer is a multistage process in its most reductive form involves initial mutational events followed by changes in gene expression leading to the selected clonal proliferation of the precancerous cell. Neoplasia appears to exhibit multiple characteristics including increase selective lesion growth (through sustained cell proliferation and /or resistance to apoptosis), the induction of angiogenesis, enabling replicative immortality, activation of factors that influence invasion and metastasis, evasion of normal growth suppression, modulation of energy metabolism, and the avoidance of attack by the immune system. The multistage nature and characteristics of the process have been extensively examined with regard to molecular, cellular, tissue, and organ events.

ACKNOWLEDGMENTS

The editor and authors recognize the contributions of previous authors of this chapter: John H. Weisburger (1st edition), Gary M. Williams and John H. Weisburger (2nd to 4th editions), Henry C. Pitot III and Yvonne P. Dragan (5th and 6th editions).

GENETIC TOXICOLOGY DEFINITION

Genetic toxicology is the study of genetic damage to the hereditary material that results in genetic alterations. Included in this broad definition are chemical and physical agents that cause mutagenicity, or transmissible genetic alterations, and genotoxicity. In contrast to mutagenicity, genotoxicity covers a broader spectrum of endpoints, including DNA damage such as DNA strand breaks and DNA adduct biomarkers (both pro-mutagenic and non-mutagenic), unscheduled DNA synthesis (UDS), and sister chromatid exchanges (SCEs); these are all measures of genotoxicity, as opposed to mutagenicity because they are not themselves transmissible from cell to cell or generation to generation. Genotoxicity also encompasses the mechanisms by which DNA damage occurs and the cellular responses to that damage. All of these effects can be assessed directly by measuring the interaction of agents with DNA or more indirectly through the assessment of DNA repair or the production of gene mutations or chromosome alterations. Standardized assay outcomes that detect mutations in populations of cells and/or organisms have been applied to systematic hazard classifications of chemicals under the United Nations Globally Harmonized System of Classification and Labelling of Chemicals (GHS). Under GHS, the chemical hazards associated with germ cell mutagenicity are assigned to one of two hazard categories: (1) substances known to induce heritable mutations (subcategory 1A) or regarded as if they induce heritable mutations (subcategory 1B) in the germ cells of humans; and (2) substances which cause concern that they may induce heritable mutations in the germ cells of humans (UN, 2015).

It is worth mentioning that in the last decades, there has been an increased emphasis on the role of epigenetic changes that control gene expression through DNA methylation and histone modifications in the production of altered phenotypes (Watson and Goodman, 2002; LeBaron et al., 2010; Dearfield et al., 2017). Although these epigenetic changes can be transmitted between generations, these are also fluid and adaptive, are not mutations by definition as they do not involve changes in DNA sequence, and have

not been observed to lead to amended point-of-departure values for risk assessment (Hamilton, 2011; Alyea et al., 2014).

In this chapter, we will discuss the history of the development of the field of genetic toxicology, the cellular pathways that counteract DNA damage on a daily basis, the use of genetic toxicology data in cancer and genetic risk assessments, the mechanisms underlying genetic toxicology assays, the assays that can be used for detecting genotoxic endpoints, the use of the same assays for better understanding mechanisms of mutagenesis, and new methods for the assessment of genetic alterations. This field of toxicology is evolving rapidly, and a review of its past and present state will set the stage to allow for a consideration of what are likely next major landmarks.

HISTORY OF GENETIC TOXICOLOGY

The field of genetic toxicology can be considered to have its roots in the pioneering work of H.J. Muller (1927), who showed that x-rays could induce mutations in the fruit fly, *Drosophila*. In his studies, he showed not only that radiation exposure could increase the overall frequencies of mutations but also that the types of mutations induced were exactly the same in effect, or phenotype, as those observed in the absence of radiation exposure. Thus, the induced mutagenic responses should be assessed in relation to background mutations. As a conclusion to this study of radiation-induced mutations, Muller predicted the utility of mutagenesis studies not only for the study of mutations themselves but also for gene mapping approaches.

Karl Sax (1938) built upon Muller's original studies of radiation-induced mutations by showing that x-rays could also induce structural alterations to chromosomes in *Tradescantia* pollen grains. Sax and his colleagues, notably in the absence of knowledge of DNA structure and chromosomal organization, showed that at least two critical lesions in a nuclear target are required for the production of an exchange within (intrachromosome) or between (interchromosome) chromosomes. We know now that the lesions identified by Sax are DNA double-strand breaks, base damages, or multiply damaged sites that are clusters of damages within one or two helical turns of DNA (reviewed by Ward, 1988). In addition, Sax and colleagues (Sax, 1939; Sax and Luippold, 1952) showed that the yield of chromosome aberrations was reduced if the total dose of x-rays was delivered over extended periods of time or split into two fractions separated by several hours. These observations led to the concept of restitution of radiation-induced damage, which was later recognized as involving specific DNA repair processes (see below).

Consideration of the genetic effects of exogenous agents on cells was expanded to include chemicals in 1946, when Charlotte Auerbach and colleagues reported that mustard gas could induce mutations in *Drosophila* and that these mutations were phenotypically similar to those induced by x-rays (Auerbach and Robson, 1946). Thus, the field of chemical mutagenesis was initiated to run in parallel with studies of radiation mutagenesis. These original studies of Auerbach (actually conducted in 1941) are placed in a historical and biological perspective by the delightful review of Geoffrey Beale (1993).

Although the scientific value of the analysis of mutations in *Drosophila* was clear, there was an impression that the extrapolation to predict similar effects in human populations was too wide a step. Thus, a research effort of great magnitude was initiated to attempt to assess radiation-induced mutations in mice. This effort resulted in the publication by William Russell (1951) of data on x-ray–induced mutations using a mouse-specific-locus mutation assay. These data clearly showed that the type of results obtained with *Drosophila* could be replicated in a mammalian system. The mouse tester strain developed for the specific-locus assay has recessive mutations at seven loci coding for visible mutations, such as coat color, eye color, and ear shape. This homozygous recessive tester strain can be used for identifying recessive mutations induced in wild type genes at the same loci in mice treated with radiation or chemical mutagens. It was noteworthy that the mutation rate for x-ray–induced mutations in germ cells was similar in mouse and *Drosophila*. Subsequent studies by Liane Russell and colleagues showed that chemicals could induce mutations at the same seven loci (Russell et al., 1981).

Over the next 20 years, genetic toxicologists investigated the induction of mutations and chromosomal alterations in somatic and germ cells, largely following exposures to radiation, but increasingly using chemical mutagens as well. The ability to grow cells in vitro, either as primary cultures or as transformed cell lines, enhanced these quantitative studies. The in vitro culture of human lymphocytes, stimulated to re-enter the cell cycle by phytohemagglutinin, greatly expanded the information on the assessment of chromosomal alterations in human cells (Hsu, 1979). It also became feasible to use cytogenetic alterations in human lymphocytes as a biodosimeter for assessing human exposures to ionizing radiations (Bender and Gooch, 1962).

Two events during the 1970s served to expand the utility of mutagenicity data into the realm of risk assessment. The Millers and their colleagues (Miller and Miller, 1977) showed that chemical carcinogens could react to form stable, covalent derivatives with DNA, RNA, and proteins both in vitro and in vivo. In addition, they reported that these derivatives could require the biotransformation of the parent chemical to form reactive metabolites. This metabolism is required for some chemicals to become mutagens and carcinogens. Metabolic capability is endogenous in vivo, but most in vitro cell lines do not express this capacity. To overcome this for in vitro mutagenicity studies, Heinrich Malling and colleagues developed an exogenous metabolizing system based on a rodent liver homogenate (S9) (Malling and Frantz, 1973; Malling, 2004). Although this exogenous metabolism system has had utility, it does have drawbacks related to species and tissue specificity and loss of cellular compartmentalization. The development of transgenic cell lines containing P450 genes has overcome this drawback to some extent (Sawada and Kamataki, 1998; Crespi and Miller, 1999).

The second development in the 1970s that changed the field of genetic toxicology was the development by Bruce Ames (Ames et al., 1975) of a simple, inexpensive mutation assay with the bacterium *Salmonella typhimurium*. This assay can be used to detect chemically induced reverse mutations in several histidine mutant strains and can include the exogenous metabolizing S9 system described above. The Ames assay, as it is generally called, has been expanded and modified to enhance its performance as discussed below (under section "Gene Mutations in Prokaryotes"). The assay has been used extensively, especially for hazard identification, as part of the cancer risk assessment process. This use was based on the assumption that carcinogens were mutagens and that cancer required mutation induction. This latter dogma proved to be somewhat inhibitory to the field of genetic toxicology because it provided a framework that was too rigid. Nonetheless, over the decade of the mid-1970s to mid-1980s somewhere on the order of 200 short-term genotoxicity and mutagenicity assays were developed for screening potentially carcinogenic chemicals. The screens included mutation induction, chromosomal damage, DNA damage, DNA repair, and cell killing or other genotoxic activities.

Several international collaborative studies were organized to establish the sensitivity and specificity of a select group of assays

as well as to assess interlaboratory variation (IPCS, 1988). Most assays were able to detect carcinogens or noncarcinogens with an efficiency of about 70% as compared with the outcome of two-year cancer bioassays (Preston, 1999a). The concordance between standard battery of in vitro genotoxicity assays and cancer bioassays was addressed to some extent by Tennant et al. (1987), who compared the effectiveness of four individual and well-characterized short-term assays to identify carcinogens. Again, this battery predicted about 70% of known carcinogens with the concordance of each individual assay was approximately 60%. The authors concluded that no battery of tests improved substantially on the overall performance of the *Salmonella* assay. Subsequently, the lack of a tight correlation between carcinogenicity and mutagenicity (and the converse, non-carcinogenicity and non-mutagenicity) was found to be due to the fact that some chemicals were not directly mutagenic, but instead induced changes necessary for tumor development indirectly by, for example, clonally expanding preexisting mutant cells (i.e., tumor promotion), inflammation, or through the production of reactive oxygen species. Such chemicals are referred to as nongenotoxic to contrast them with genotoxic mechanism of action. In the context of the mechanism of their mutagenicity, it is preferable to distinguish between DNA-reactivity and its correlate non-DNA-reactivity. Emphasis has recently been placed on identifying mechanisms whereby not directly mutagenic chemicals can be involved in tumor production. Those identified include cytotoxicity with regenerative cell proliferation, mitogenicity, receptor-mediated processes, changes in methylation status, immunosuppression, and alterations in cell–cell communication.

In the last two decades, the field of genetic toxicology has moved away from the short-term assay approach for assessing carcinogenicity to a much more mechanistic approach, fueled by the advances in molecular biology, analytical techniques, and statistical methodologies. In addition, genetic toxicology as a field has made significant advances from a primarily qualitative assessment of hazard without consideration of the dose to a quantitative examination of the dose–response to facilitate risk assessment (Gollapudi et al., 2013; Johnson et al., 2014; Gollapudi, 2017). The ability to manipulate and characterize DNA, RNA, and proteins and to understand basic cellular processes and how they can be perturbed has advanced enormously over this period. Knowing how to take advantage of these technical developments is paramount. This chapter addresses these changes in approach to genetic toxicology: the assays for qualitative and quantitative assessment of cellular changes induced by chemical and physical agents, the underlying molecular mechanisms for these changes, and how such information can be incorporated into cancer and genetic risk assessments.

HEALTH IMPACT OF GENETIC ALTERATIONS

Mutations are permanent, transmissible alterations in DNA sequences that result in changes to the amount or structure of genetic material in the cell. Both small (i.e., one or few base-pair changes of a single gene) and large scale (i.e., changes affecting multiple genes) DNA alterations can lead to mutations. Mutagenicity refers to induction of mutations and the substances that induce mutations are referred to as mutagens. Clastogenicity refers to the process of inducing chromosomal breaks, and clastogens are the substances that induce chromosomal breakage. Clastogenicity can lead to chromosomal deletions and rearrangements and these events can lead to mutations provided that they are not lethal to the cell harboring them. Substances that induce numerical changes in chromosome complement of a cell through loss or gain of whole chromosome(s) are referred to as aneugen and these substances induce aneugenicity through changes in the ploidy (i.e., aneuploidy) of the normal chromosome complement of the cell. The importance of mutations and chromosomal alterations for human health is evident from their roles in genetic disorders, including birth defects and cancer. Mutations in both germ cells and somatic cells need to be considered when an overall risk resulting from mutations is assessed. However, mutations are also the underlying mechanism of variability and adaptation, the basis for evolution.

Somatic Cells

Somatic mutations arise in the genomes of all normal dividing and transformed cells as a result of endogenous and exogenous processes and stressors (Greenman et al., 2007). An association between mutation and cancer has long been evident, such as through the correlation between the mutagenicity and carcinogenicity of chemicals, especially in biological systems that have the requisite metabolic activation capabilities. Moreover, human chromosome instability syndromes and DNA repair deficiencies are associated with increased cancer risk (Friedberg, 1985). Recent evidence shows that an average cancer genome contains about 10^3 to 10^4 point mutations, 10 to 10^2 small insertions or deletions, and 1 to 10 large-scale chromosome rearrangements (including copy-number alterations) (Zhang and Pellman, 2015). Most somatic mutations are likely to be "passengers" that do not contribute to oncogenesis (Greenman et al., 2007). Overall, approximately 13,000 unique mutations from 5000 genes and ~340,000 tumors have been catalogued with the new next-generation sequencing (NGS) techniques (Bell, 2010). However, cancers are specifically driven by the accumulation of "driver" mutations in a subset of consensus "cancer genes" that confer growth advantage to cells; more than 410 mutated genes implicated in cancer development have been identified (Futreal et al., 2004; Greenman et al., 2007; Stratton et al., 2009; Bell, 2010; Pleasance et al., 2010). "Cancer genes" exhibit attributes that confer advantages with the capacity to generate their own mitogenic signals, the evasion of apoptosis, the resistance of exogenous growth-inhibitory signals, reprogramming of energy metabolism, evading immune destruction, cellular proliferation without limits, and acquisition of angiogenic, invasive and metastatic properties (Hanahan and Weinberg, 2000; Hanahan and Weinberg, 2011); these are classified into 12 signaling pathways that regulate three core cellular processes: cell fate, cell survival, and genome maintenance (Vogelstein et al., 2013). In turn, these characteristics and dysregulated pathways allow cancer pathogenesis through genomic instability and mutability that drive tumor progression, and elevated inflammatory responses that are tumor-promoting (Hanahan and Weinberg, 2011).

The advances in the NGS technologies have enabled the comprehensive characterization of somatic mutations in large number of tumor samples, allowing for new insight and revealing unanticipated complexities in the patterns of somatic alterations in cancers (Watson et al., 2013). These advances challenge the previously held belief of a linear process driven by serially acquired new mutations, including base pair substitutions, small insertions and deletions of bases, chromosomal rearrangements, and gains and losses in gene copy number (Vogelstein and Kinzler, 1993). In a study of 210 diverse human cancers, more than 1000 somatic base pair mutations have been identified along with the evidence for "driver" mutations in approximately 120 genes that contribute to the development of the studied cancers (Greenman et al., 2007). New NGS evidence suggests that most point mutations (including small insertion or

deletion events) in cancer genomes are passengers that do not contribute to cancer development, and their patterns reflect the underlying mutational processes (Zhang and Pellman, 2015).

New NGS data show that cancer genomes have histopathologically distinct cancer subtypes of the same organ site and often have divergent underlying genomic alterations (Watson et al., 2013). The recent landmark, large-scale cancer genomics analysis, applied to almost five million somatic mutations identified in 7042 cancer samples, has provided insight into the global signatures of mutational processes in human cancer (Alexandrov et al., 2013). Each of the cancer types had at least two active mutational signatures, while some cancers, including liver and uterus, had up to six distinct mutational signatures; mutational signatures include substitutions, indels, dinucleotide substitutions, *kataegis*, and strand bias. The analysis revealed 27 distinct mutational signatures; 22 of these mutational signatures were validated and etiology was proposed for 11 of the 22 validated mutational signatures. Two major mutational signatures were associated with age of patient at cancer diagnosis and exhibited clear features of C-to-T transitions at CpG sites; these major somatic mutations were hypothesized to reflect mutations due to normal cellular processes such as deamination of 5-methylcytosine of CpG sites and DNA replication errors. These background mutations were proposed to account for the majority of somatic mutations prior to neoplastic development (Alexandrov et al., 2013). Two mutational processes were associated with the activity of endogenous APOBEC family of deaminases; these exhibit predominantly C-to-T and C-to-G mutations at TpC sites and have been observed in 17% of all examined cancer samples. Distinct mutational signatures were associated with BRCA1/2 mutations in breast and pancreatic cancers; DNA mismatch repair defects in colorectal cancers; hypermutation of the immunoglobulin genes in chronic lymphocytic leukemia; and recurring polymerase ε mutations in uterine and colorectal cancers among others. Mutational signatures were also confirmed for ultraviolet light exposure as to C-to-T transitions at CpC or TpC sites, and for "tobacco smoking signature" as C-to-A transversions.

Cancer cytogenetics have revealed chromosomal alterations, including deletions, translocations, inversions, and amplifications, and these changes have been implicated in many human leukemias and lymphomas as well as in some solid tumors (Rabbitts, 1994; Zhang et al., 2010). Also, somatic mutations in the noncoding gene promoter regions have been recognized as genetic alterations in multiple cancer types (Piraino and Furney, 2016). Cancer genomes often harbor multiple large-scale chromosomal alterations including extensive or whole-chromosome aneuploidy, telomere-bound copy-number alterations, chromosomal rearrangements, and complex karyotypes within the same region of chromosomes (Zhang and Pellman, 2015). Compared with the analysis of point mutations, the analysis of chromosomal alterations is very preliminary, but suggests that chromosomal breakage occurs frequently at centromeres and is enriched either in early-replicating, gene-rich regions or late-replicating, gene-poor regions, possibly reflecting different underlying mechanisms (Zhang and Pellman, 2015). On the phenotypic level, the large-scale copy-number alterations and chromosomal rearrangements can cause varying changes in fitness and are tumor type–dependent. Some aneuploidies are recurrent in certain tumor types and almost certainly under positive selection (Gordon et al., 2012).

Initial evidence that mutation plays a role in cancer has come from molecular studies of acquired somatic mutations in oncogenes, or positive growth regulators, and inactivation of tumor-suppressor genes. Oncogenes are genes that stimulate the transformation of normal cells into cancer cells (Bishop, 1991). They originate when genes called proto-oncogenes, involved in normal cellular growth and development, are genetically altered. Normal regulation of cellular proliferation requires a balance between factors that promote growth and those that restrict it. Mutational alteration of proto-oncogenes can lead to overexpression of their growth-stimulating activity, whereas mutations that inactivate tumor-suppressor genes, which normally restrain cellular proliferation, free cells from their inhibitory influence (Hanahan and Weinberg, 2000, 2011).

The action of oncogenes is genetically dominant in that a single active oncogene is expressed, even though its normal allele is present in the same cell. Proto-oncogenes can be converted into active oncogenes by point mutations or chromosomal alterations. Base pair substitutions in *ras* proto-oncogenes are found in many human tumors (Bishop, 1991; Barrett, 1993; Croce, 2008). Among chromosomal alterations that activate proto-oncogenes, translocations are especially prevalent (Rabbitts, 1994, Croce, 2008; Zhang et al., 2010). For example, Burkitt lymphoma involves a translocation between the long arm of chromosome 8, which is the site of the *c-MYC* oncogene, and chromosome 14 (about 90% of cases), 22, or 2. A translocation can activate a proto-oncogene by moving it to a new chromosomal location, typically the site of a T-cell receptor or immunoglobulin gene, where its expression is enhanced. A similar translocation-based mechanism also applies to various other hematopoietic cancers. Alternatively, the translocation may join two genes, resulting in a protein fusion that contributes to cancer development. Fusions have been implicated in other hematopoietic cancers and some solid tumors (Rabbitts, 1994; Croce, 2008; Zhang et al., 2010). Like translocations, other chromosomal alterations can activate proto-oncogenes, and genetic amplification of oncogenes can magnify their expression (Bishop, 1991; Croce, 2008).

Mutational inactivation or deletion of tumor-suppressor genes has been implicated in many cancers. Unlike oncogenes, the cancer-causing alleles that arise from tumor-suppressor genes are typically recessive in that they are not expressed when they are heterozygous (Evans and Prosser, 1992). However, several genetic mechanisms, including mutation, deletion, chromosome loss, and mitotic recombination, can cause loss of heterozygosity (LOH), in which the normal allele is inactivated or eliminated creating a locus with no normal gene function. LOH leads to the expression of the recessive cancer gene in a formerly heterozygous cell (Cavenee et al., 1983; Turner et al., 2003; Reliene et al., 2007). The inactivation of tumor-suppressor genes has been associated with various cancers, including those of the eye, kidney, colon, brain, breast, lung, and bladder (Fearon and Vogelstein, 1990; Marshall, 1991). Mutations in a tumor-suppressor gene called *P53*, located on chromosome 17, occur in many different human cancers, and molecular characterization of *P53* mutations has linked specific human cancers to mutagen exposures (Harris, 1993; Aguilar et al., 1994; Royds and Iacopetta, 2006).

In the simplest model for the action of tumor-suppressor genes, two events are considered to be required for the development of retinoblastoma, a tumor of the eye, because both normal alleles must be inactivated or lost (Knudson, 1997). In sporadic forms of the cancer without family history of disease, the two genetic events occur independently, but in familial cases, such as familial retinoblastoma, the first mutation is inherited, leaving the need for only a single additional event for expression. The strong predisposition to cancer in the inherited disease stems from the high likelihood that a LOH will occur by mutation, recombination, or aneuploidy in at least one or a few cells in the development of the affected organ. The simple model involving two events and a single pair of alleles cannot explain all observations concerning tumor-suppressor genes because many cancers involve more than one tumor-suppressor

gene. For example, the childhood kidney tumor called Wilms tumor can be caused by damage in at least three different genes (Marshall, 1991), and colorectal carcinomas are often found to have lost not only the wild-type *P53* tumor-suppressor gene but also other tumor-suppressor genes (Fearon and Vogelstein, 1990; Stoler et al., 1999). Moreover, a single mutation in a tumor-suppressor gene, even though not fully expressed, may contribute to carcinogenesis. For example, a single *P53* mutation in a developing colorectal tumor may confer a growth advantage that contributes to the development of the disease (Venkatachalam et al., 1998). Subsequent LOH will increase the growth advantage as the tumor progresses from benign to malignant (Fearon and Vogelstein, 1990). In this regard (mutation and selection), carcinogenesis has been likened to an evolutionary process, with genomic instability providing the substrate and with growth advantage as the selection pressure (Gatenby and Vincent, 2003; Fischer et al., 2004).

Many cancers involve both activation of oncogenes and inactivation of tumor-suppressor genes (Fearon and Vogelstein, 1990; Bishop, 1991; Croce, 2008). The observation of multiple genetic changes supports the view that cancer results from an accumulation of genetic alterations and that carcinogenesis is a multistep process (Kinzler and Vogelstein, 1996; Hahn et al., 1999; Stoler et al., 1999; Croce, 2008). At least three stages have been defined in carcinogenesis: initiation, promotion, and progression (Barrett, 1993). *Initiation* involves the induction of a genetic alteration, such as the mutational activation of a *ras* proto-oncogene either spontaneously or by a mutagen. It is an irreversible step that starts the process toward cancer. *Promotion* involves cellular proliferation in an initiated cell population. Promotion can lead to the development of benign tumors such as papillomas. Agents called promoters stimulate this process. While some mutagens can also act as tumor promoters, most promoters are not mutagens. Promotion is a reversible process and generally requires the continuous exposure to the promoter. *Progression* involves the accumulation of additional irreversible genetic changes and it is marked by increasing genetic instability and malignancy. More recent studies are beginning to change this view, leading to the concept of acquired capabilities (Hanahan and Weinberg, 2000). In their *Hallmarks of Cancer*, Hanahan and Weinberg (2000) describe a set of six acquired characteristics that are essential for the formation of all tumors irrespective of tumor type and species. These characteristics are broadly described as follows: self-sufficiency in growth signals, insensitivity to antigrowth signals, evading apoptosis, limitless replicative potential, sustained angiogenesis, and tissue invasion and metastasis. It seems probable that there is no specific order for obtaining these characteristics. Hanahan and Weinberg have revisited their hallmarks concept, and, based on progress in the field over the past decade, they have added two emerging hallmarks of potential generality to their existing six (Hanahan and Weinberg, 2011). These are reprogramming of energy metabolism and evading immune destruction. In addition, they describe genome instability and inflammation as general features that underlie their now eight hallmarks (Hanahan and Weinberg, 2011).

Genomic instability is a feature of all cancers, with the great majority having a large number of chromosomal and gene mutations and aneuploidies. Gene mutations, chromosome aberrations, and aneuploidy are all implicated in the development of cancer. Mutagens and clastogens contribute to carcinogenesis as initiators. Their role does not have to be restricted to initiation, however, in that mutagens, clastogens, and aneugens may also contribute to the multiple genetic alterations that characterize progression or the development of acquired capabilities. Other agents that contribute to carcinogenesis, such as promoters, need not be mutagens. However, the role of mutations is critical, and analyzing mutations and mutagenic effects is essential for understanding and predicting chemical carcinogenesis. Currently, there is a debate on the fraction of cancers arising from random mutations during normal cell division versus those mutations contributed by environmental and lifestyle factors, with some authors proposing that nearly two-thirds of cancer-causing mutations occur spontaneously during cell proliferation (Tomasetti and Vogelstein, 2017).

Germ Cells

The relevance of gene mutations to health is evident from the many disorders that are inherited as simple Mendelian characteristics (Mohrenweiser, 1991). About 1.3% of newborns suffer from autosomal dominant (1%), autosomal recessive (0.25%), or sex-linked (0.05%) genetic diseases (Sankaranarayanan, 1998; Elespuru and Sankaranarayanan, 2007; National Research Council [NRC], 2007a, 2007b). Molecular analysis of the mutations responsible for Mendelian diseases has revealed that almost half of these mutations are base pair substitutions; of the remainder, most are small deletions (Sankaranarayanan, 1998; Elespuru and Sankaranarayanan, 2007). In contrast to somatic mutations, common structural variants in the germ cells have been determined with NGS methods to be deletions, tandem duplications, transpositions, inversions, and insertions that affect only a small region of the genome and are nonoverlapping (Zhang and Pellman, 2015).

Many genetic disorders (such as cystic fibrosis, phenylketonuria, Tay-Sachs disease) are caused by the expression of recessive mutations. These mutations are mainly inherited from previous generations and are expressed when an individual inherits the mutant gene from both parents. New mutations make a larger contribution to the incidence of dominant diseases than to that of recessive diseases because only a single dominant mutation is required for expression. Thus, new dominant mutations are expressed in the first generation. If a dominant disorder is severe, its transmission between generations is unlikely because of reduced fitness. For dominants with a mild effect, reduced penetrance, or a late age of onset, the contribution from previous generations is undoubtedly larger than it is for mutations with severe early expression. Estimating the proportion of all Mendelian genetic diseases that can be ascribed to new mutations is not straightforward; a rough estimate is 20% (Shelby, 1994).

Besides causing diseases that exhibit Mendelian inheritance, gene mutations undoubtedly contribute to human disease through the genetic component of disorders with a complex etiology (Sankaranarayanan et al., 1999; Sankaranarayanan, 2006). Some 3% (United Nations Scientific Committee on the Effects of Atomic Radiation [UNSCEAR], 2001) or 5% to 6% (Sankaranarayanan, 1998) of infants are affected by congenital abnormalities; if one includes multifactorial disorders that often have a late onset, such as heart disease, hypertension, and diabetes, the proportion of the population affected increases to more than 60% (Sankaranarayanan, 1998, 2006; UNSCEAR, 2001). Such frequencies are necessarily approximate because of differences among surveys in the reporting and classification of disorders. A higher prevalence would be found if less severe disorders were included in the tabulation. Nevertheless, such estimates provide a sense of the large impact of genetic disease.

Sensitive cytogenetic methods have led to the discovery of minor variations in chromosome structure that have no apparent effect. On the contrary, other relatively minor structural chromosome aberrations cause fetal death or serious abnormalities. Aneuploidy (gain or loss of one or more chromosomes) also

contributes to fetal deaths and causes disorders such as Down syndrome. About four infants per 1000 live births have syndromes associated with chromosomal abnormalities, including translocations and aneuploidy. The majority of these syndromes (about 85%) result from trisomies (Griffin, 1996; Nagaishi et al., 2004; NRC, 2007a, 2007b). Most of the adverse effects of chromosomal abnormalities occur prenatally. It has been estimated that 5% of all recognized pregnancies involve chromosomal abnormalities, as do about 6% of infant deaths and 30% of all spontaneous embryonic and fetal deaths (Mohrenweiser, 1991; Nagaishi et al., 2004). Among the abnormalities that have been observed, aneuploidy is the most common, followed by polyploidy. Structural aberrations constitute about 5% of the total. Unlike gene mutations, many of which are inherited from the previous generation, about 85% of the chromosomal anomalies observed in newborns arise de novo in the germ cells of the parents (Mohrenweiser, 1991). The frequency of aneuploidy assessed directly in human sperm is 3% to 4%; about 0.4% are sex chromosome aneuploidies (Martin et al., 1991, 1996). The frequency of aneuploidy in human oocytes is about 18% (Martin et al., 1991).

As the field of oncology incorporates NGS approaches into tumor and germline analyses, comparisons of tumor to the germline genomes may identify variants associated with susceptibility to cancer as well as other hereditary diseases (Stadler et al., 2014). These new advances in NGS, together with identification of genetic sequence variants associated with common diseases, have the potential to shift the paradigm of personalized medicine, providing estimates of personal disease risk and the germline genetic risk assessment to more precisely guide medical management (Abul-Husn et al., 2014). For example, meta-analysis of somatic and germline DNA sequence biomarker variants of esophageal cancer has identified a number of germline polymorphism markers in *TP53* and nucleotide excitation DNA repair pathways associated with survival and recurrence following treatment of esophageal cancer (Findlay et al., 2015).

CANCER AND GENETIC RISK ASSESSMENTS

Cancer Risk Assessment

Genotoxicity and mutagenicity testing is a prerequisite to the assessment of carcinogenic and hereditary risks associated with chemical exposures (Moolenaar, 1994; EPA, 1996, 2005; ECHA, 2016; Eastmond, 2017). Harmonized strategies for mutagenicity testing for chemical risk assessment have been developed (Ashby et al., 1996; Cimino, 2006; Eastmond et al., 2009; MacGregor et al., 2015a). Chemicals are screened in a battery of mutagenicity and genotoxicity assays to identify carcinogenic agents with a mutagenic mode of action (MOA). Mutagenic carcinogens share common characteristics and typically produce positive gene mutation and chromosomal alteration in multiple in vitro and in vivo test systems (EPA, 2005). Mutagenic carcinogens are also active at multi-organ level, in different species, as well as at low-dose exposures across multiple doses (Tennant and Spalding, 1996). An adverse outcome pathway for mutagenic liver carcinogens was recently proposed involving a number of essential key events (KEs) (Becker et al., 2017; Moore et al., 2018). The sequence of KEs leading to cancer is initiated with a formation of pro-mutagenic DNA adduct/lesion. Following insufficient or misrepair of the adduct, a KE of an early mutation in critical gene(s) is expected that is to be followed by a KE of cellular proliferation and clonal expansion leading to an adverse outcome of hepatocellular carcinoma. However, it is important to remember that a substance that has induced tumors in animal bioassays is not necessarily acting via a mutagenic MOA (Dearfield and Moore, 2005). Moreover, accumulated evidence has demonstrated that somatic mutations are brought about by the combination of genetic effects and cellular proliferation either by (1) increasing genetic damage so there are more errors produced during DNA replication; or (2) increasing the rate of DNA replication that increases the likelihood that spontaneous errors in DNA become fixed in daughter cells (Ames and Gold, 1990; Cohen and Ellwein, 1991; Cohen et al., 1991; Cohen and Arnold 2011; Tomasetti and Vogelstein, 2015; Tomasetti et al., 2017). Thus, for carcinogen risk assessment, it is important to understand impacts not just on genotoxicity, but also on cellular proliferation rates, and to distinguish substances that are DNA-reactive from substances that act by mechanisms increasing cellular proliferation. For substances that are not DNA-reactive, mechanisms that can increase cell proliferation include receptor-mediated responses (e.g., enzyme induction CAR, PXR, AhR) and non-receptor mediated MOA (e.g., cytotoxicity leading to regeneration) (Becker et al., 2017). These MOAs can also be organized into adverse outcome pathway frameworks that provide a basis for research, regulatory toxicology testing and risk assessment, among other applications such as in eventual regulatory decision-making.

When assessing carcinogenic risks to humans, evaluation of complex genotoxicity databases should involve a weight-of-evidence approach in which studies are critically evaluated based on their quality, reproducibility and consistency, significance of genetic alternations, phylogenic relevance to humans, type (in vivo vs. in vitro), and relevance of the route of chemical administration (Eastmond, 2017). Using these guidelines, the most weight is allocated to high-quality in vivo studies of gene and chromosome mutations in humans and mammals exposed via a physiologically relevant oral, dermal, or inhalation routes (Eastmond, 2017). Following evaluation and assessment of the chemical dataset, the weight-of-evidence approach is used to reach conclusions about chemical's genotoxicity potential.

The formalized process for conducting a cancer risk assessment has many variations based on national requirements and regulations. Historically in the United States, the default has been linear extrapolation from the rodent bioassay tumor data to exposure levels consistent with human environmental or occupational exposures (NRC, 1983, 1994; EPA, 1986). The assessment of risk has required the application of a series of default approaches for extrapolation, for example, from laboratory animals to humans, from high to low exposures, from intermittent to chronic lifetime exposures, and from route to route of exposure. Subsequently, approaches based on mechanistic data were published in *Guidelines for Carcinogen Risk Assessment* to inform the risk assessment process, particularly for dose–response assessment and risk characterization at low environmental exposures (EPA, 2005). These United States Environmental Protection Agency's (EPA) cancer risk assessment guidelines provide a framework that utilizes MOA approach as the tool to organize the set of key events (KEs) required for a chemical to produce a tumor (Sonich-Mullin et al., 2001; EPA, 2005; Preston and Williams, 2005). The EPA guidelines invoke a linear extrapolation and dose–response models in case of mutagenic MOA and as a default in case of an absence of sufficient MOA information. MOA is a biologically plausible series of chemical-specific key events starting with exposure and proceeding through the interaction of an agent with a cell, subsequent physiological, tissue, or organ changes, and resulting in an adverse effect or outcome (Sonich-Mullin et al., 2001; Dellarco and Fenner-Crisp, 2012). Furthermore, this approach is more consistent with frameworks developed around a MOA/human relevance concepts (MOA framework) by the

World Health Organization/International Programme on Chemical Safety (IPCS) (Boobis et al., 2006; Meek et al., 2014a, 2014b) and International Life Sciences Institute (ILSI) (Meek et al., 2003).

The IPCS MOA framework has been now widely adopted around the world into regulatory guidance (European Food Safety Authority, European Chemicals Agency, U.S. EPA, Joint FAO/WHO Meeting on Pesticide Residues), and hazard characterization/risk assessment, although variability in its use and conclusions has led to different interpretations of the sufficiency of evidence in support of hypothesized and alternative MOAs (Dourson et al., 2013; Becker et al., 2017). The MOA framework is an analytical approach where different lines of evidence are organized, linked, and integrated at different levels of biological organization into a more efficient, hypothesis-driven approach to safety evaluation that informs a human health risk assessments of chemical exposures (Dellarco and Fenner-Crisp, 2012; Meek et al., 2014a; Becker et al., 2017). The MOA framework has been extended to enable the evaluation for species concordance of effects in the context of environmental levels of exposure (Meek et al., 2014b).

The MOA framework continuously evolves to increase transparency and defensibility of decisions as well as systematic analysis of a weight-of-evidence supporting of all postulated chemical MOAs (Becker et al., 2017). The qualitative analysis in support of a MOA includes the scoping of potential MOAs and consideration of qualitative comparative weight-of-evidence of the supporting data. The latest addition to the framework involves quantitative weight-of-evidence confidence scoring based on the evolved Bradford Hill considerations (Meek et al., 2014a, 2014b; Becker et al., 2015, 2017); this latest methodology includes evaluation of the positive, negative, or contradictory studies as well as strength of such evidence/counter-evidence that facilitates identification of the best supported MOA. The evolved Bradford Hill considerations for causality evaluate (1) biological concordance; (2) essentiality of key events; (3) dose–response concordance, temporal concordance, and incidence concordance of empirical observation; (4) consistency among different biological contexts; and (5) analogy (consistency across structurally significant chemicals) to promote better common understanding, consistency in use as well as confidence in particular MOA (Meek et al., 2014b). Lines of evidence are evaluated and integrated to elucidate whether a substance acts to induce cancer primarily via DNA reactivity or whether it acts by mechanisms that increase cell proliferation (e.g., receptor-mediated or cytotoxicity leading to regeneration). Once an animal MOA and its KEs are established, qualitative and quantitative comparisons between experimental animals and humans are made to determine whether the MOA is likely operative in humans and, if so, whether it can result in a more refined hazard and dose–response assessment (Dellarco and Fenner-Crisp, 2012; Meek et al., 2014a, 2014b).

Genetic Risk Assessment

Historically, genetic risk assessment has been interpreted in a qualitative, dichotomous "yes" or "no" manner without analysis of dose-response relationships. It has been recognized that these qualitative outcomes of in vitro genotoxicity tests do not adequately predict the outcomes of rodent carcinogenicity bioassays or in vivo genotoxicity assays. The traditional "parallelogram approach" has involved estimation of the frequency of genetic alterations in human germ cells by using rodent germ cell and somatic cell data (Brewen and Preston, 1974; Sobels, 1982; Brusick, 1994; Preston et al., 1995; UNSCEAR, 2001; Eastmond, 2012, 2017).

New in vitro and in vivo data have demonstrated the existence of nonlinear/bilinear dose responses for genotoxic effects, defined as a dose–response curve with a slope not significantly different from zero gradient below the estimated threshold or Break Point Dose (BPD); within the BPD region, no significant difference in mutant frequency between the spontaneous background of control and the low-dose exposure region following treatment with DNA-reactive agents (Klapacz et al., 2016; White and Johnson, 2016; Wills et al., 2016). Recent international multi-sector efforts have been undertaken to improve human health risk assessment for DNA-reactive chemicals utilizing a quantitative dose–response relationships from in vitro and in vivo genetic toxicology data sets to support risk characterization and risk management (Gollapudi et al., 2013; Johnson et al., 2014; MacGregor et al., 2015a, 2015b; White and Johnson, 2016).

Under the general framework for risk assessment with DNA-reactive chemicals, the identification of key elements and factors should take place such as: (1) hazard assessment; (2) assessment of exposure to genotoxicants; (3) methods for dose and effect assessment; (4) risk characterization strategies for genotoxic environmental chemicals; and (5) monitoring of environmental genotoxicant levels (Lewtas et al., 1994; Favor et al., 1995). Under this framework presented in Fig. 9-1, the risk assessment can be applicable to most situations; furthermore, the risk characterization measures require implementation by the regulatory agencies as well as monitoring of environmental exposure situations by risk managers (NAS, 1983; Lewtas et al., 1994; Favor et al., 1995; MacGregor et al., 2015a).

This framework focuses on minimization of the genotoxic risk and protecting against the risk of developing diseases (MacGregor et al., 2015a). A number of quantitative approaches for analyzing dose–response curves for genotoxic effects and deriving point-of-departure (PoD) metrics have been evaluated that are based on the research data; these PoD metrics are: the no-observed-genotoxic-effect-level (NOGEL) or the highest dose tested for which there is no significant increase in genotoxic effect compared to control; the threshold effect level (BPD or Td) or the dose at which the slope changes from zero (horizontal) to positive, with its standard error forming the confidence bounds (90% CI); the benchmark dose (BMD_{10}) or the dose that produces 10% increase over the fitted background; BMD_{1SD} (the change in response corresponding to one standard deviation) or 10% excess risk for individuals below and above the 2nd and 98th percentiles, respectively; and slope-transition-dose (STD) or the lowest dose for which the lower bound of the 95% confidence interval of the slope exceeds zero (Gollapudi et al., 2013; Johnson et al., 2014).

The PoD descriptors were determined for a number of chemicals, including the data-rich, prototypical S_N1 and S_N2-type alkylating agents (Gocke and Muller, 2009; Gollapudi et al., 2013; Cao et al., 2014; Johnson et al., 2014; Ji et al., 2016). NOGEL, $BMDL_{10}$, and $BMDL_{1SD}$ PoD metrics can be readily calculated from most gene mutation and chromosomal damage studies and the $BMDL_{10}$ values were often lower than the other PoDs (Johnson et al., 2014; MacGregor et al., 2015a). Analysis of obtained PoD values showed that these different approaches are complementary with respect to their advantages and limitations; have values within the same order of magnitude; and demonstrate more variability for the in vivo assays. The $BMDL_{10}$ is considered a satisfactory PoD matrix for the analysis of genotoxic effects, as it typically yields a good fit to the data, generally provides the most conservative value, is flexible, and can be readily applied to a wide range of datasets. It should be noted that many DNA-reactive chemicals have been demonstrated to exhibit nonlinear/bilinear dose responses for genotoxic effects, such as formaldehyde, vinyl acetate, and propylene oxide (Swenberg et al., 1983; Albertini and Sweeney, 2007; Albertini, 2013).

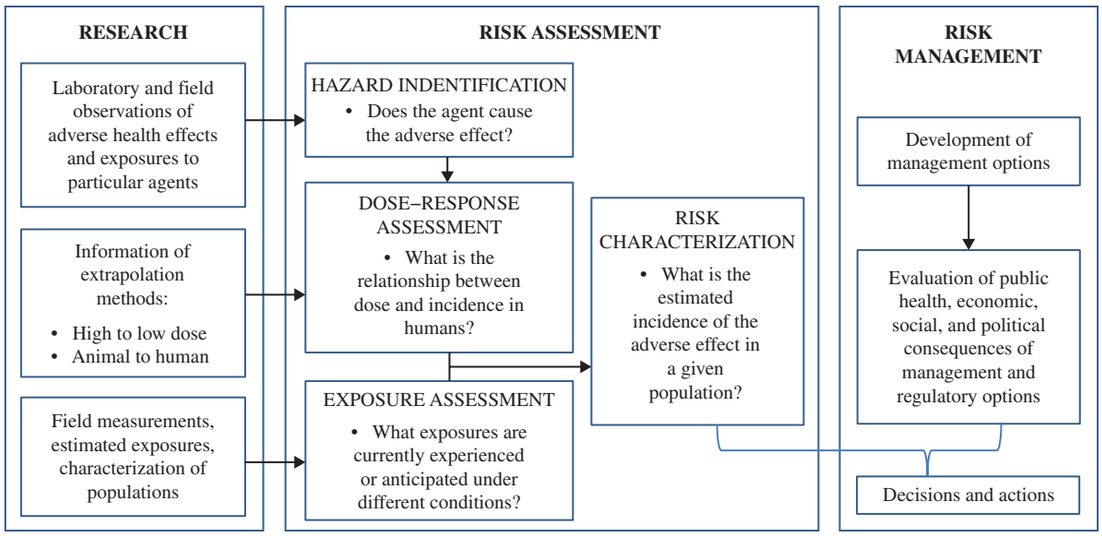

Figure 9-1. *Elements of risk assessment and risk management processes of the quantitative risk assessment framework for DNA-reactive agents.* (Reproduced with permission from MacGregor et al., 2015a.)

Once the genotoxic PoD values are obtained from in vivo test systems or target tissues with relevance to human health, appropriate extrapolation method(s) and uncertainty/assessment/safety factors need to be applied for the risk assessment. The choice of appropriate methods and assessment factors depends on knowledge of the mechanisms behind the dose–response relationships, the critical MOA information for DNA-reactive agents, and the entire weigh-of-evidence of the toxicological dataset (MacGregor et al., 2015b). The mechanistic information used by authoritative bodies in their risk assessment has included: critical involvement of non-DNA targets; contribution of DNA repair mechanisms; exceeded detoxification capacity; disruption of enzymes involved in DNA synthesis or replication; chemical reactivity or properties unlikely to occur in vivo; inadequate uptake or toxicokinetics limiting distribution to target; mutational spectrum in tumor genes similar to those in untreated animals; structural similarities to similar threshold-acting chemicals; secondary or indirect origin of the observed damage; and species and tumor-specific non-genotoxic MOA (MacGregor et al., 2015b). Parameters and safety factors that need to be evaluated in order to minimize the uncertainty in the assessment include: (a) species differences and allometric scaling; (b) differences in absorption, distribution, metabolism, and pharmacokinetics; (c) differences in duration of exposure; (d) severity of toxicity endpoint; (e) variability among individuals; and (f) uncertainty in PoD (MacGregor et al., 2015b). When data that permit assessment of these parameters/factors are not available, default adjustment factors of up to 10,000-fold can be applied to extrapolate to the acceptable human exposure levels. Knowledge of exposure, metabolism, and pharmacokinetics can help refine this extrapolation and reduce the assessment factor values by replacement with the experimentally determined parameters. Knowledge of a particular DNA adduct formed, its stability, its pro-mutagenic potential, its miscoding properties, the efficiency and fidelity of DNA repair in a particular tissue or cell type, and the replication rates of tissue or cell types can be used as a surrogate marker of a biologically effective dose (MacGregor et al., 2015b).

Overall, the derived genotoxic PoD values can be combined with appropriate assessment factors for the purpose of conducting the quantitative risk assessment for DNA-reactive agents. This approach will facilitate the derivation of reference doses below which there are no additional significant risk to human health as well as margin of exposure values useful for evaluating human health risk and regulatory decision making.

FORMATION OF DNA DAMAGE AND DNA DAMAGE RESPONSE PATHWAYS

DNA Damage

Preservation of genome integrity is central to cellular survival and successful propagation of hereditary material, yet all organisms sustain a certain number of background mutations as a result of limited DNA chemical stability, numerous stressors, cellular processes, and interactions with the environment (Lindahl, 1993). Endogenous and exogenous chemicals produce a wide array of DNA lesions such as covalent DNA base adducts, cross-links between DNA bases or between DNA bases and proteins, and single- and double-strand breaks. DNA replication, transcription, or erroneous incorporation of ribonucleotides into DNA can also be a source of spontaneous mutation and genome instability (Echols and Goodman, 1991; Datta and Jinks-Robertson, 1995; McElhinny et al., 2010). Ubiquitously present ultraviolet radiation, ionizing radiation, and exogenous hydrocarbons also present threats to genomic stability (Fig. 9-2).

In order to maintain the genome integrity and to assure accurate duplication of genomic information by DNA and RNA polymerases, this damage must be faithfully repaired and/or addressed by posttranslational activation of cell cycle networks and transcriptional networks for apoptosis/cell death (Guerard et al., 2015; Thomas et al., 2015; Klapacz et al., 2016). The understanding of the cellular mechanisms acting within the background mutation regions of the genotoxic dose–response curve can facilitate better risk characterization from exposures to DNA-reactive chemicals, the determination of points of departure (PoDs) metrics for genotoxic effects that minimize genotoxic risk and protect against disease development (Gollapudi et al., 2013; Johnson et al., 2014; MacGregor et al., 2015a, 2015b; Klapacz et al., 2016). The aim of this section is to introduce the topic of DNA damage because such damage is the molecular initiating event for the formation of genetic alterations

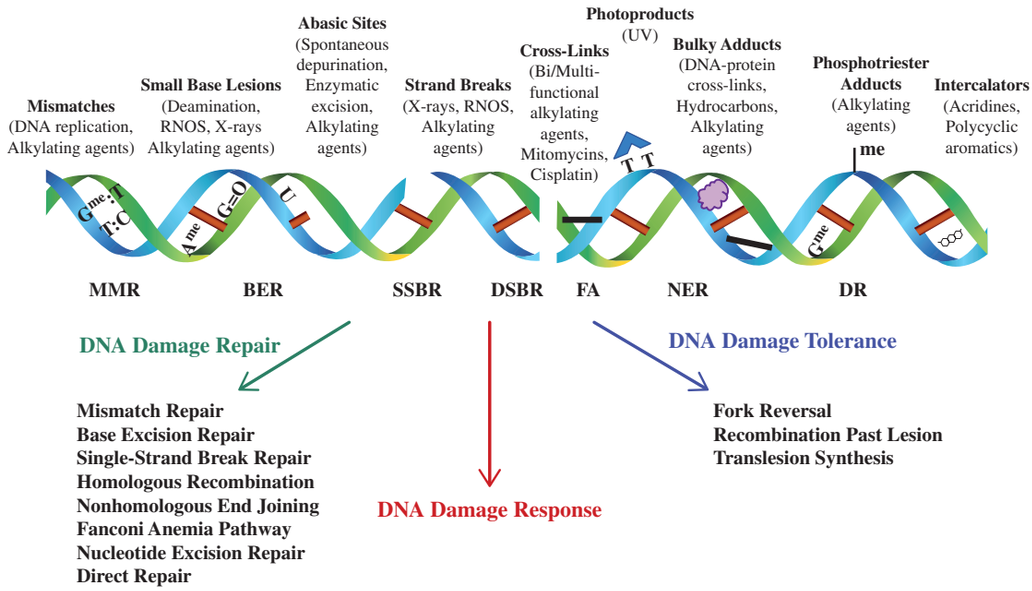

Figure 9-2. *Cellular mechanisms of DNA repair and damage tolerance to spontaneous and induced DNA damage.*

and genotoxicity in general. For an expressed mutation, several key events must occur downstream from the initial DNA adduct formation, including insufficient adduct repair, DNA replication, and cell division (Pottenger and Gollapudi, 2010). Much greater detail can be found in recent reviews that are referenced within this section.

Background DNA Damage Genomes sustain a continuous damage load due to numerous stressors, cellular metabolism, and limited chemical stability of DNA (Lindahl, 1993, 2000). The electrophilic by-products of endogenous metabolism include reactive oxygen species formed as by-products of cellular oxygen consumption (such as superoxide $O_2^{\cdot}$, hydroxyl free radicals $^{\cdot}OH$, and hydrogen peroxide), nitric oxide and its metabolites causing nitrosative stress and pro-inflammatory responses, lipid peroxidation by-products, aldehydes, and alkylators. Endogenous processes produce oxidized and alkylated bases, single- and double-strand breaks, interstrand cross-links, hydrolytic and enzymatic deamination of cytosine and 5-methylcytosine leading to uracil and thymine, respectively. In the absence of any significant exogenous exposures, the steady-state background DNA damage load was estimated at ≥50,000 lesions per cell (Swenberg et al., 2011). The spontaneous daily damage load includes ~30,000 noninstructional and pro-mutagenic abasic sites resulting from spontaneous purine losses or enzymatic adduct/base cleavage, alkylated (*N7*-methyl-dG) and oxidized (8-oxo-dG) bases, formaldehyde adducts, acrolein-dG adducts, and various etheno-purines (Lindahl, 1993; Swenberg et al., 2011). This significant and ubiquitous background of pro-mutagenic DNA background damage is similar to that caused by exogenous DNA-reactive agents and is likely causative for the normal range of background mutations (Swenberg et al., 2011; Sharma et al., 2014).

The process of DNA replication itself is error-prone as one in about 10^6 replicated bases can be mis-inserted by replicative polymerases, or the polymerase can slip at repetitive sequences resulting in as small insertion–deletion loops (IDLs). However, the frequency of mis-inserted bases in replication is not the sole determinant of the spontaneous mutation frequency. Living cells reduce the rate of polymerase error appreciably through error recognition and repair processes (Johnson, 2010). A high-fidelity polymerase may make one error in a million bases while copying roughly 300 base pairs per second, but polymerase proofreading and mismatch correction then lower the error rate as much as 1000-fold (Johnson, 2010). The evolutionarily conserved mismatch repair pathway further corrects base pair mismatches as well as IDLs that escape the proofreading activity of DNA polymerases (Modrich and Lahue, 1996; Schofield and Hsieh, 2003); mismatch repair contributes about 1000-fold to the overall DNA replication fidelity (Jaworski et al., 1995; Jiricny, 2006). The result is a low spontaneous mutation rate of the DNA replication process. A recent study based on the sequencing of 19 *Escherichia coli* genomes in a 40,000-generation experiment estimated the rate of spontaneous base pair substitutions to be 8.9×10^{-11} per base pair per generation (Wielgoss et al., 2011). Finally, high levels of transcription in all organisms stimulate a wide variety of mutation types that reflect multiple molecular mechanisms (Jinks-Robertson and Bhagwat, 2014).

Ionizing Radiation Electromagnetic waves that carry enough energy to ionize or remove electrons from an atom are defined as ionizing radiation (IR). Major exposure sources of general populations to IR include background waves, nuclear medicine, occupational exposure, industrial and consumer sources (NCRP, 2008). X-rays, γ-rays, neutrons, and α and β particles are types of IR that can produce radiochemical DNA damage either by direct or indirect mechanisms causing single- and double-strand breaks, abasic sites and a broad range of oxidative base damages from indirect creation of free radicals (Goodhead, 1994; Wallace, 1994; Ward, 1994; Cadet et al., 2011). The signature of IR exposure is the induction of DNA clustered damaged sites, defined as two or more lesions within one to two helical turns of DNA (Eccles et al., 2011). Clustered damage can either be associated with double-strand breaks, oxidized base lesions or abasic sites or with single-strand breaks, oxidized base lesions, abasic sites. These multiple lesions can be formed in DNA from the same radiation energy deposition event (Blaisdell et al., 2001). The relative proportions of these different classes of DNA damage vary with type of radiation. For example, single-strand breaks and base damages predominate with x-rays, for

which ionization density is sparse, whereas increased frequencies of single- and double-strand breaks occur as a result of exposure to α particles for which ionization is dense. The 7,8-dihydro-8-oxo-2′-deoxyguanosine (8-oxo-dG) base damage is considered as a biomarker for IR exposure and radiosensitivity (Erhola et al., 1997; Roszkowski and Olinski, 2012). Other base lesions such as thymine glycols, hypoxanthine, 1,N^6-ethenoadenine, or 3,N^4-ethenocytosine were also quantified following IR exposure (Le et al., 1998; Olipitz et al., 2012). It has been demonstrated that the modified histone γ-H2AX can be used as a sensitive biomarker of IR exposure following formation of DNA double-strand breaks (Nakamura et al., 2006; Mah et al., 2010; Shee et al., 2013). The alkaline comet assay is also routinely used to measure DNA strand break damage following patient exposure to IR (Alapetite et al., 1999; Dusinska and Collins, 2008; Borrego-Soto et al., 2015).

Low-dose ionizing radiation is known to induce radioadaptive responses in vitro as well as in mice in vivo. The importance of dose-rate as the critical determinant of a genotoxic and adverse outcome has been demonstrated and presumably reflects saturation of the DNA repair and damage response capabilities at high-dose exposures leading to adverse outcomes including mutation. No accumulation of DNA damage such as base lesions and micronuclei, sequence rearrangements, and gene expression of several radiation-sensitive genes following low-dose subacute exposure to 10.5 cGy γ-radiation was seen in mice (Olipitz et al., 2012). This IR dose corresponds to approximately 400-fold increase over background dose, inducing formation of additional ~400 base lesions per cell. Meanwhile, when the same total amount of radiation was delivered in one acute dose, DNA double-strand breaks and DNA stress responses were detected.

Ultraviolet Light Ultraviolet (UV) light is a type of electromagnetic nonionizing radiation with the wavelength range shorter than that of the violet end of the visible spectrum, but longer than that of x-rays. Our bodies use UV light to make vitamin D, but DNA is certainly one of its key ubiquitous targets; high UV exposure causes skin burns and can even lead to cancer. UV radiation induces two of the most predominant and cytotoxic DNA lesions, cyclobutane-pyrimidine dimers (CPDs) and 6-4 photoproducts (6-4PPs) as well as their Dewar valence isomers. These lesions and biological responses to these lesions in various organisms have been well characterized and are described below (Friedberg et al., 1995). Organisms have developed a number of repair and tolerance mechanisms to counteract UV-induced DNA damage (Sinha and Häder, 2002). Photoreactivation with the help of the enzyme photolyase is one of the most important and frequently occurring repair mechanisms in a variety of microorganisms. Excision repair plays an important role in eukaryotic DNA repair of UV-induced damage. In addition, mechanisms such as mutagenic repair, dimer translesion bypass, homologous recombination repair, cell-cycle checkpoints, apoptosis, and certain alternative repair pathways are also operative in various organisms to counteract consequences of UV exposures.

Chemical Agents The major classes of DNA-reactive chemicals include polycyclic aromatic hydrocarbons, arylamines and nitroaryl hydrocarbons, aflatoxins, small alkylators, oxidating, reducing and deaminating chemicals, halogenated hydrocarbons, DNA-DNA and DNA-protein cross-linkers, strand breakers, and DNA intercalators; these are presented in Figure 9-2. Chemicals can produce DNA alterations either directly by DNA-reactive mechanisms of adduct formation or indirectly by intercalation of polycyclic, aromatic, and planar chemicals between the base pairs (Heflich, 1991). The conversion of DNA adducts or other structural modifications into gene and chromosomal mutations by errors of DNA replication on the damaged template, or occasionally by errors of DNA repair, can lead to cells being initiated along the key events pathway to the adverse outcome of cancer.

Many electrophilic chemicals react with nucleophilic sites within DNA, forming covalent addition products called biomarker DNA adducts, or some other DNA structural modifications. The DNA bases involved and the positions on DNA bases can be specific for a given chemical; base pairing can protect certain base positions from the adduction. Such specificity of DNA damage can result in a spectrum of mutations that is chemical-specific (Dogliotti et al., 1998; Jarabek et al., 2009). Some alkylated bases can mispair, causing mutations when DNA is replicated, other adducts are cytotoxic, while others can be both mutagenic and cytotoxic; importantly the most common alkylating adduct at *N7* position of dG is not mutagenic. Ubiquitous alkyl adducts at the *N3* and *N7* positions of purines destabilize the *N*-glycosidic bond between the base and sugar backbone making these modified bases more susceptible to depurination into abasic sites (Wyatt and Pittman, 2006; Swenberg et al., 2011). Abasic sites are noninstructional and pro-mutagenic as the insertion of incorrect bases across from the abasic sites can cause mutations (Laval et al., 1990). The most abundant alkyl adduct produced by alkylating agents is at the *N7* position of guanine, a site that has the highest negative electrostatic potential in DNA (Pullman and Pullman, 1981; Beranek, 1990). However, *N7* C1-C3 alkyl guanine adducts are not considered to be cytotoxic or mutagenic as they do not block DNA replication and are well tolerated in the cells (Boiteux and Laval, 1983; Larson et al., 1985; Boysen et al., 2009; Philippin et al., 2014).

Bulky DNA adducts that distort DNA double helix, such as cisplatin, metabolites of benzo(*a*)pyrene, or *N*-2-acetylaminofluorene, are recognized and repaired by excision repair in a similar way to UV damages (Gillet and Scharer, 2006). These bulky adducts impede progress of DNA and RNA polymerases, causing replication fork collapse or stalled transcription, respectively. If unrepaired, these lesions can be bypassed during DNA replication in an error-prone or error-free manner by translesion synthesis (TLS).

Indirect intercalators such as acridine compounds (9-aminoacridine, ethidium bromide, etc.) and other planar molecules such as daunomycin, doxorubicin, and thalidomide in repetitive DNA sequences have been associated with the induction of frameshift mutations in which one or two base pairs have been gained or lost (Ferguson and Denny, 1990; Hoffmann et al., 2003).

DNA Repair and Tolerance Pathways

The thousands of the steady-state background DNA lesions are readily repaired in cells by an integrated network of DNA repair pathways that includes direct repair (DR), base excision repair (BER), nucleotide excision repair (NER), mismatch repair (MMR), nonhomologous end-joining of double-strand breaks (NHEJ), homologous repair pathway (HR), and Fanconi Anemia (FA) pathway; these are presented in Figure 9-2. Among these repair activities, base excision repair is considered one of the most active, handling thousands of abasic sites, alkylated, oxidized and deaminated bases, single-strand breaks and nicks per day. These pathways also have overlapping repair substrates; for example, the most predominant abasic sites are also processed by homologous recombination between two similar or identical DNA sequences, nucleotide excision repair, or translesion synthesis that allows the DNA replication past unrepaired DNA lesions (Boiteux and Guillet 2004; Covo et al., 2004; Adar et al., 2009). The basic principles underlying DNA repair processes involve damage recognition, followed by either direct reversal of the damage (sealing

of strand breaks or removal of alkyl adducts from DNA bases) or excision of damage that involves sequential steps of repair DNA synthesis, and ligation of strands. DNA repair is usually error-free, but there may be rare events where the misrepair will result in genotoxic outcomes (Wiktor-Brown et al., 2008; Sukup-Jackson et al., 2014; Klapacz et al., 2016). DNA repair influences the genotoxic outcome, the dose–response of mutation and chromosome damage following exposure to DNA-reactive agents at all exposure levels (Kirsch-Volders et al., 2000; Parry et al., 2000; Guerard et al., 2015; Thomas et al., 2015).

In contrast, if the sustained damage is extensive, the cell can undergo apoptosis (programmed cell death), effectively avoiding it becoming a mutant cell (Evan and Littlewood, 1998). If the damage is less severe, it can be repaired by a range of processes that are a part of generalized and complex cellular response networks; these processes can return the damaged DNA to its undamaged state by error-free post-replication damage avoidance pathway utilizing HR, or to an improved, but still altered, state involving the Radiation Sensitivity Proteins RAD6 and RAD18 protein complex responsible for Proliferating Cell Nuclear Antigen (PCNA) modification and activation of translesion synthesis (TLS) (Hoege et al., 2002; McIntyre et al., 2006). During TLS, a family of prokaryotic and eukaryotic TLS polymerases, such as the human Y-family polymerases eta, iota, kappa, and Rev1, can bypass lesions that otherwise would block replication by the normal processive DNA polymerases (Rattray and Strathern, 2003; Prakash et al., 2005). These conserved polymerases have the ability to bypass specific DNA lesions or groups of lesions. The result of the lesion bypass can be an insertion of incorrect dNTP or a correct one depending on the induced lesion and the particular bypass polymerase.

This chapter presents a brief outline of the major classes of DNA repair and tolerance pathways (Fig. 9-3); much greater detail can be found in the reviews provided for each section and general reviews by Van Houten and Albertini (1995), Friedberg (2000), Krokan et al. (2000), Wood et al. (2005), Bansbach and Cortez (2011), Chatterjee and Siede (2013), and Coleman and Huang (2016).

Base Excision Repair (BER) The base excision repair (BER) pathway is one of the most active DNA repair pathways in cells operating at all cell cycle stages. BER repairs non-bulky oxidative, deaminated, and alkylated modifications to bases or the sugar phosphate backbone as well as abasic sites both in the nucleus and mitochondria (Chatterjee and Walker, 2017). BER involves five key enzymatic steps (Fig. 9-3A) to remove the initial DNA lesion and restore the original sequence, starting with (i) lesion recognition and excision of damaged base or inappropriate base by *N*-glycosylase; (ii) incision of the phosphodiester backbone at the resulting abasic site by apurinic/apyrimidinic (AP) endonuclease; (iii) termini clean-up to permit repair synthesis and/or nick ligation; (iv) gap-filling to replace the excised nucleotide by DNA polymerase; and (v) sealing of the final nick by DNA ligase enzymes.

BER is initiated by a class of lesion-specific enzymes called DNA glycosylases that recognize and cleave the damaged base to an abasic site (Lindahl, 1976; Demple and Harrison, 1994; Seeberg et al., 1995; Wood, 1996; McCullough et al., 1999; Sung and Demple, 2006); at least 11 different DNA glycosylases have been identified. Glycosylases are known to share overlapping substrates; for example, 8-oxoguanine glycosylase (OGG1), nei endonuclease VIII-like NEIL1, and NEIL3 glycosylases can all process 8-oxo-dG. DNA glycosylases initiate BER by either short-patch (one nucleotide) or long-patch (often 6 to 13 nucleotides) BER. The abasic sites formed by DNA glycosylases are recognized and processed by AP endonucleases, such as APE1 or Apn1 to create incision of the phosphodiester backbone (Wood et al., 2001). DNA synthesis to fill the repair patch is completed by DNA polymerases, such as Pol β for short-patch repair, and processive Pol δ or Pol ε polymerases for long-patch repair. Two additional strand incision repair pathways that feed into long-patch BER have been characterized: nucleotide incision repair (NIR) where AP endonuclease directly incises 5′ to oxidized and alkylated pyrimidines (Ischenko and Saparbaev, 2002); and ribonucleotide excision repair (RER) initiated by the RNase H2 complex that incises the strand 5′ to the misincorporated ribonucleotide (Sparks et al., 2012). Finally, repair of direct or indirect single stranded DNA breaks is undertaken by the single-strand break repair (SSBR) pathway that feeds into BER. SSBR is divided into four different processes beginning with detection of a break, followed by DNA end processing, gap-filling, and finally ligation of the backbone (Fan and Wilson 2005). The importance of the BER pathway is highlighted by the fact that deficiencies in the core BER enzymes are incompatible with life and result in embryonic lethality and cell death (Xanthoudakis et al., 1996; Tebbs et al., 1999; Fung and Demple, 2005). Defects in BER enzymes lead to reduced

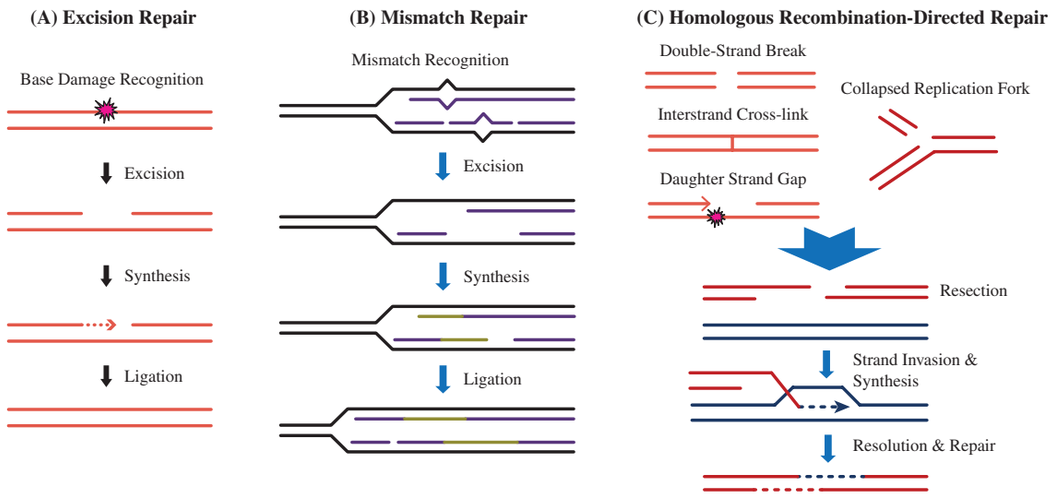

Figure 9-3. *Schematics of basic steps of key DNA repair pathways.* (**A**) Excision repair; (**B**) mismatch repair; (**C**) homologous recombination-directed DNA repair.

cell survival, elevated mutation rates, DNA-damaging agent hypersensitivities, and altered cellular responsiveness to relevant chemotherapeutics, such as alkylators (e.g., temozolomide), nucleoside analogs (e.g., 5-fluorouracil), and ionizing radiation (Kim and Wilson, 2012).

Nucleotide Excision Repair (NER) The nucleotide excision repair (NER) pathway is a highly conserved pathway that recognizes and removes bulky DNA lesions that distort DNA double helix and impede progress of DNA and RNA polymerases, causing replication fork collapse or stalled transcription, respectively (Lommel et al., 1995; Gillet and Scharer, 2006; Jiang and Sancar, 2006). Substrates for NER include UV-induced lesions; cisplatin and hydrocarbon base adducts; chemicals in tobacco smoke, aflatoxin B1, endogenous lipid peroxidation products; and ROS-induced base modifications (cyclopurines). NER uses about 30 proteins to remove the damage-containing 25 to 30 base pairs long oligonucleotide from DNA (Reardon and Sancar, 2005; Reed, 2011). The basic four steps of NER involve: (i) damage recognition and incision on both sides of the lesion, (ii) excision, (iii) repair synthesis, and (iv) ligation of the nicks (Fig. 9-3A). If unrepaired, these lesions can be bypassed in an error-prone manner by TLS polymerases. The characterization of these steps has been facilitated by the use of rodent mutant cell lines and cells from individuals with syndromes characterized by the UV-hypersensitivity, neurodevelopmental abnormalities, and skin cancers (Broughton et al., 2001). The defects in NER pathway are genetically linked to a group of autosomal recessive human diseases such as xeroderma pigmentosum (XP), Cockayne syndrome (CS), and photosensitive form of trichothiodystrophy. The cardinal feature of such patients is an extremely high incidence of UV-related cancers.

NER consists of a general pathway termed global genomic repair (GGR) that removes lesions from the entire genome and a specialized pathway referred to as transcription-coupled repair (TCR). These pathways differ in the mechanism of damage recognition, but share the same mechanism for removal and repair of the damage. In GGR, the xeroderma pigmentosum group C-complementing, or XPC complex, is the initial damage recognition factor that recognizes the damage-induced structural change in DNA, binds to the strand opposite the adduct, mediates the recruitment of transcription factor II human (TFIIH) complex, and initiates excision repair (Maillard et al., 2007; Min and Pavletich, 2007; Scharer, 2007). In TCR, stalled RNA polymerase II (RNAP) serves as the damage recognition step (Mellon and Hanawalt, 1989). In both pathways, TFIIH complex, containing XP type B and D, XPB (3′-5′) and XPD (5′-3′) helicases respectively, promotes the opening of DNA duplex around the adduct (Coin et al., 2007; Sugasawa et al., 2009; Mathieu et al., 2010). XPF-ERCC1 (for XP type F and excision repair cross complementation group 1) and XP type G (XPG) endonucleases are then responsible for dual incision 5′ and 3′ to the DNA damage, respectively (Evans et al., 1997). After the dual incision event and removal of the damage-containing oligonucleotide fragment, DNA Pols δ, ε, or κ carry out gap-filling synthesis in cooperation with replication factor C (RFC) and proliferating cell nuclear antigen (PCNA) (Tang and Chu, 2002; Mocquet et al., 2008; Ogi et al., 2010). Finally, the nick is sealed in by ligase I or III complexes (Aboussekhra et al., 1995; Araújo et al., 2000; Moser et al., 2007; Mocquet et al., 2008).

Double-Strand Break Repair Cell survival and genome integrity are seriously compromised by the presence of broken chromosomes. Despite these consequences, double-strand breaks are exploited by cells to control a number of biological processes such as initiation of V(D)J recombination during antibody diversification, recombination of genetic material during meiosis, and decatenation of DNA molecules by topoisomerase II (Helleday et al., 2007). When double-strand breaks occur, the ends of the DNA are mostly not directly ligatable. To cope with the damage, all organisms have evolved several double-strand break repair mechanisms, of which NHEJ and HR are the most prominent (Shinohara and Ogawa, 1995; Critchlow and Jackson, 1998; Haber, 2000; Sonoda et al., 2006; Mladenov and Iliakis, 2011). Alternative error-prone double-strand break repair pathways, namely alternative end joining (alt-EJ) and single-strand annealing (SSA), have been recognized to compete for repair with classical HR (Fig. 9-3C) (Decottignies, 2013; Ceccaldi et al., 2015). These pathways are largely similar across a broad range of species from yeast to humans, although the most frequently utilized one differ among species. Unrepaired double-strand breaks activate DNA damage repair (DDR) networks that allow either recognition of the break, activation of cellular checkpoints and DNA repair, or induction of apoptosis (Misteli and Soutoglou, 2009). Chromatin plays a crucial role in the regulation of DDR and double-strand break repair (Lemaître and Soutoglou, 2014) with phosphorylated histone H2AX (γH2AX) serving as an early response following double-strand break formation (Rogakou et al., 1998, 1999). Formed γH2AX/MCD1 complex then either recruits p53 binding protein 1 (53BP1) to direct repair toward NHEJ, or BRCA1 to direct repair toward HR. MRN complex and ATM participate in both HR and NHEJ (Paull and Gellert, 1998, 2000). Recent evidence also suggests that small non-protein-coding RNAs are generated at the sites of DNA damage and control DDR network responses (d'Adda di Fagagna, 2014).

Homologous Recombination (HR) Eukaryotes undergo homologous recombination (HR) between similar or identical DNA sequences as part of their normal activities both in germ cells (meiotic recombination) and somatic cells (mitotic recombination) (Zheng et al., 2011). In eukaryotes, the process has been characterized most extensively for yeast, and these processes have been largely conserved in higher eukaryotes (Johnson et al., 1999; Krejci et al., 2003; West, 2003; Cahill et al., 2006). HR is the principal mode of double-strand break repair in the S and G_2 phases of the cell cycle and is facilitated by the proximity of a sister chromatid with essentially the identical sequence as the broken chromosome (Fig. 9-3C). HR has been proposed to be initiated by the recognition of double-strand break by the Mre11-Rad50-Nbs1 (MRN) complex that acts as a break sensor and recruits ataxia-telangiectasia mutated (ATM) kinase to the site of damage (Stracker and Petrini, 2011). The initiating step involves the processing of the DNA ends immediately adjacent to the double-strand break and the production of a 3′-single-stranded tail by exonucleases or helicase activity. This is followed by the location of regions of homology, strand invasion with D-loop formation, and branch migration whereby the single-stranded tail invades an undamaged homologous DNA molecule and Holliday junction DNA complex is formed; Holliday junction is cross-shaped structure that forms when two double-stranded DNA molecules become separated into four strands in order to exchange segments of genetic information. DNA synthesis and the resolution of the Holliday junction by its cleavage produce two DNA molecules (with or without a structural crossover). Additional models have also been proposed (Haber, 2000; Jasin and Rothstein, 2013). A detailed description of the specific enzymes known to be involved can be found in Shinohara and Ogawa (1995), Cahill et al. (2006), Helleday et al. (2007), Hiom (2010), and Jasin and Rothstein (2013).

Nonhomologous End-Joining (NHEJ) Classical nonhomologous end-joining (NHEJ) pathway joins two broken DNA ends in close spatial proximity to each other by direct re-ligation (Lieber

et al., 2003). NHEJ does not require extensive sequence homology or genetic recombination and the repair is influenced by regions of microhomology of to 14 base pairs. NHEJ is the major double-strand break repair pathway in higher eukaryotes (Burma et al, 2006). NHEJ can occur throughout cell cycle, but it predominates in the G_0/G_1 and G_2 phases (Lieber, 2010). NHEJ is also an integral part of the V(D)J recombination, generating the vast antibody diversity and T-cell receptor proteins, while ensuring genomic stability (Malu et al., 2012).

NHEJ entails three main steps: recognition of the two-ended strand breaks; processing to remove non-ligatable termini; and joining of the two ends. To initiate NHEJ, the Ku70/Ku80 heterodimer binds directly to the two broken ends, and recruits the DNA-dependent protein kinase DNA-PKcs to facilitate the alignment of the broken ends (Mimori et al., 1986; Cary et al., 1997; Ramsden and Gellert, 1998). DNA-PKcs activates DNA endonucleases that trim the 3′ and 5′ single-stranded overhangs at the DNA ends to reveal complementary nucleotide stretches (Ma et al., 2002; Neal and Meek, 2011). This processing often results in nucleotide loss. In instances where short nucleotide gaps remain after microhomology-mediated annealing, DNA Pols μ and λ fill in the small gap segments (Mahajan et al., 2002; Fan and Wu, 2004). Finally, ligase IV complex stimulates end joining to complete the repair process (Ahnesorg et al., 2006).

Fanconi Anemia (FA) Pathway Fanconi anemia (FA) DNA excision repair pathway is involved in the repair of interstrand cross-links (ICLs) produced by cross-linking chemicals such as cisplatin, diepoxybutane, and mitomycin C (Coleman and Huang, 2016). ICLs can interfere with cellular processes requiring separation of the two DNA strands, such as DNA replication and transcription. Unrepaired ICLs can lead to mutations, chromosome breakage, and mitotic catastrophe. In addition to recognition and repair of ICLs, the complex FA pathway orchestrates cooperation of other DNA repair processes to complete ICLs repair process, such as HR, NER, and TLS. Individuals with FA protein defects exhibit hypersensitivity to cross-linking agents, developmental defects, bone marrow failure, and cancer predisposition.

Mismatch Repair (MMR) The principal function of mismatch repair (MMR) system is the maintenance of genome integrity by correcting base pair mismatches and IDLs that escape the proofreading activity of DNA polymerases, and mismatches that occur after HR events (Modrich and Lahue, 1996; Jiricny, 1998; Schofield and Hsieh, 2003; Jun et al., 2006). MMR also responds to certain forms of DNA damage caused by alkylating agents, cisplatin, ROS, and UV radiation where it targets base pair mismatches following base mis-incorporation opposite DNA lesion (Earley and Crouse, 1998; Colussi et al., 2002; Mazurek et al., 2002; Stojic et al., 2004). In this role of DNA damage surveillance, MMR proteins activate cell cycle checkpoints and apoptosis through interaction with signaling kinases such as ATM (or ataxia-telangiectasia mutated), ATR (or ataxia telangiectasia and Rad3 related), and checkpoint kinases CHK1, and CHK2 (Wang and Qin, 2003; Stojic et al., 2004; Yoshioka et al., 2006; Liu et al., 2010). Individuals with defective MMR exhibit mutator phenotype (or increase in the mutation rate); microsatellite (or repetitive DNA sequence motifs) instability at mono-, di-, and trinucleotide repeats resulting in length changes of these motifs; and predisposition to hereditary Lynch cancer syndrome, also known as hereditary non-polyposis colorectal cancer (HNPCC), at an early age (Ionov et al., 1993; Shibata et al., 1994; Kolodner, 1995; Lynch and Lynch, 2000).

The principal steps of prokaryotic and eukaryotic MMR are damage recognition and binding to the mismatch, stabilizing of the binding by the addition of other proteins, cutting the DNA at a distance from the mismatch, excision past the mismatch, resynthesis, and ligation (Fig. 9-3B). Organisms differ in their strategies to discriminate the parental template strand from the newly synthesized daughter strand. These mechanisms are understood in Gram-negative bacteria such as *E. coli* that utilize the DNA methylation at the N^6 position of adenine in 5′-GATC-3′ sequences to direct the MMR-dependent strand excision to the newly synthesized, unmethylated DNA strand (Putnam, 2016). In higher eukaryotes the strand discrimination mechanisms are not completely understood; however, MMR is associated with eukaryotic replication machinery, suggesting that this interaction facilitates strand discrimination (Modrich, 1997; Mastrocola and Heinen, 2010; Pluciennik et al., 2010). Data implicate PCNA (the "clamp") together with replication factor C (RFC) complex ("clamp loader") in early steps of eukaryotic MMR, as well as in gap repair synthesis. Following mismatch recognition, the mutS homolog (MSH) heterodimers convert to ATP-dependent sliding clamps and recruit mutL homolog (MLH) heterodimers that together coordinate daughter strand excision. MutLα complex is a latent endonuclease activated by MutSα, RFC, and PCNA in a mismatch- and ATP-dependent manner (Kadyrov et al., 2006). DNA daughter segment flanked by two-strand breaks is then removed by exonuclease 1 and finally replaced by the processive DNA synthesis machinery (Kadyrov et al., 2006).

Direct Repair (DR) The error-free direct repair (DR) mechanism is defined as the elimination of DNA and RNA damage using chemical reversion that does not require a nucleotide template, breaking of the phosphodiester backbone, or DNA synthesis (Nay and O'Connor, 2013). There are two distinct DR mechanisms in the majority of organisms: photoreactivation of UV-induced pyrimidine dimers by photolyases, and the removal of the alkyl groups from DNA and RNA by methyltransferases and dioxygenases.

Photolyases have been identified in various organisms, but were lost early in the mammalian evolution and are not present in humans (Gerkema et al., 2013). DNA photolyases repair the UV-A- and UV-B-induced major pyrimidine dimers in DNA and RNA (Kim and Sancar, 1993). Photolyases bind to DNA containing a pyrimidine dimer in a light-independent reaction and absorb a photon to initiate the splitting of the dimer into two pyrimidines (Rupert et al., 1958; Rupert, 1961; Sancar, 1994).

Methylguanine DNA Methyltransferase (MGMT) O^6-Alkylguanines are major cytotoxic and pro-mutagenic adducts produced by a variety of endogenous and exogenous alkylating chemicals (Loechler et al., 1984; Goldmacher et al., 1986; Beranek, 1990). If the cells enter S phase prior to O^6-methylguanine (O^6-MeG) repair, processive DNA polymerases commonly mispair O^6-MeG with dT resulting in O^6-MeG:T mismatch and fixation of a G:C-to-A:T transition mutation in the second round of replication (Fig. 9-4) (Ito et al., 1994). The ubiquitous methylguanine DNA methyltransferases (MGMT) remove alkyl from O^6 position of dG. The human MGMT protein is constitutively expressed, housekeeping gene that is expressed in all tissues (Pieper, 1997). In all organisms, the alkyl group (such as methyl, ethyl, propyl, butyl, benzyl, and 2-chloroethyl) is transferred via a one-step reaction to the repair protein by covalent binding to a highly conserved, active site cysteine directly restoring the DNA base and inactivating the protein (Tano et al., 1990; Grombacher et al., 1996; Margison et al., 2003; Parkinson et al., 2008). This is referred to as a "suicide mechanism" where the protein is inactivated and targeted for elimination by proteasome (Srivenugopal et al., 1996). A clear link between the levels of MGMT repair protein and the existence of thresholds for *HPRT* gene mutation induction was demonstrated in human-derived

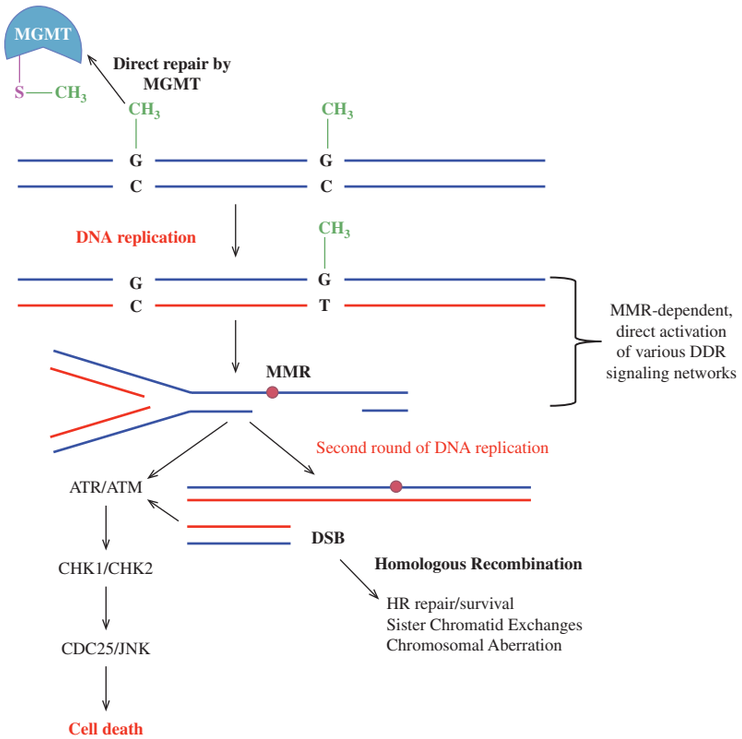

Figure 9-4. *Interactions of DNA repair and damage response pathways in the processing and repair of O^6-MeG adducts in DNA.* MGMT repair protein directly repairs O^6-MeG adducts. If unrepaired, O^6-MeG preferably mispairs with T during DNA replication leading to G:C-to-A:T transitions. Alternatively, O^6-MeG lesion induces apoptosis via the mismatch repair-dependent pathway. O^6-MeG/mismatch repair-dependent DNA damage response includes multi-DNA damage response pathway, multi-time scale signaling network activation led by early ATM, H2AX, ATR-CHK1 kinases, and p53 phosphorylation, then followed by late phosphorylation of ATM-CHK2 and JNK kinase, as well as dramatic increases in p53 levels and p53 transcriptional target. Sister chromatid exchanges and chromosomal aberrations are induced by O^6-MeG lesions via the mismatch repair-dependent pathway in the second cell cycle. The gaps and nicks present during this phase can form double-strand breaks that are handled by homologous recombination. With loss of mismatch repair activity, cells become "methylation-tolerant" accumulating mutations and escaping cell death in the presence of unrepaired O^6-MeG. (Reproduced with permission from Klapacz et al., 2016.)

AHH-1 cells (Thomas et al., 2013). When levels of MGMT are not adequate or depleted, the MMR pathway serves as a backup repair pathway by eliminating cells with O^6-MeG bases and preventing mutation (Fig. 9-4) (Duckett et al., 1996; Kaina et al., 1997; Cejka et al., 2004). O^6-alkylguanine adducts can also be repaired by NER pathway (Taira et al., 2013). Biochemical studies have revealed that O^6-MeG can be bypassed by TLS polymerases Pol η, Pol κ, and Pol ξ (Ito et al., 1994).

Alkbh Fe(II)/α-Ketoglutarate-Dependent Dioxygenases Direct repair of *N3*-cytosine and *N1*-adenine alkyl adducts in DNA and RNA has been associated with the action of alkylation protein B (AlkB) family of dioxygenases (Kataoka et al., 1983; Delaney et al., 2005; Frick et al., 2007). The AlkB enzyme was first discovered in *E. coli* and a number of its homologues (ALKBH) have been identified in humans (Aravind and Koonin, 2001; Kurowski et al., 2003). DNA adducts that are repaired by these enzymes interfere with base-pairing, block DNA replication and transcription, and trigger cell cycle checkpoints and apoptosis (Kataoka et al., 1983; Kurowski et al., 2003; Westbye et al., 2008). Dealkylation reaction catalyzed by AlkB and ALKBH occurs via transformation of α-ketoglutarate into succinate and restoration of the undamaged base (Trewick et al., 2002; Lee et al., 2005); removal of methyl adducts releases formaldehyde, removal of ethyl adducts releases acetaldehyde, whereas removal of etheno adducts releases glyoxal (Trewick et al., 2002; Delaney and Essigmann, 2004). *E. coli* AlkB mutants and Alkbh2- and Alkbh3-deficient mouse embryonic fibroblasts exhibit increased sensitivity to S_N2-type alkylating chemicals and increased mutant frequency (Delaney and Essigmann, 2004; Ringvoll et al., 2006; Nieminuszczy et al., 2009).

Translesion Synthesis (TLS) Translesion synthesis (TLS) is carried out by 11 highly conserved and specialized DNA polymerases that are lesion- and species-specific (Prakash et al., 2005). TLS involves a temporary switch from the replicative, high-fidelity polymerases to specialized, error-prone polymerases that help the cells bypass and tolerate the unrepaired damage (Moldovan et al., 2007). Common characteristics of TLS polymerases are large active sites that accommodate the damage, fewer contacts with DNA, low processivity, and lack of 3′–5′ exonuclease activity. For example, yeast and human homologues of TLS Pol η replicate past TT dimers in an error-free manner; however, these incorrectly insert dG across from thymidine in 6-4 pyrimidine dimer photoproducts causing T-to-C mutations (Masutani et al., 2000; Johnson et al., 2001). XPV (xeroderma pigmentosum variant) patients have demonstrated congenital lack of this Pol η that leads to UV-hypersensitivity and predisposition to cutaneous malignancies (Tung et al., 1996; Masutani et al., 1999; Kannouche et al., 2004). Two TLS models have been proposed: the polymerase switch model to accommodate lesion bypass, and single-strand gap-filling model that typically falls outside of S phase of cell cycle (Chatterjee and Walker, 2017). After nucleotides are incorporated across from the damaged bases, the aberrant primer termini are typically extended by Pol ζ.

DNA Damage Response (DDR) DNA damage response (DDR) networks effectively remove thousands of background DNA load and maintain a very low level of spontaneous mutagenesis (Chatterjee and Siede, 2013). DNA repair enzymes and signaling networks are regulated by DDR kinases including ATM (ataxia-telangiectasia mutated), ATR (ATM- and Rad3-Related), and DNA-PKcs (DNA-dependent protein kinases) at the sites of DNA damage via posttranslational protein modification cascades. These kinases sense the damage together with their mediator proteins, then pass the damage signal onto the transducer checkpoint kinases CHK1 and CHK2 (Bartek et al., 2001; Chen and Sanchez, 2004; Tanaka, 2010), followed by direct or indirect mediators of cell cycle progression such as p53, cell division cycle 25 CDC25A, B, or C phosphatases (Falck et al., 2001; Zhao et al., 2002; Sørensen et al., 2003). Activation of the p53 checkpoint provides the cell with a more prolonged G_1 cell cycle arrest (Bartek and Lukas, 2001). The p53 protein is phosphorylated directly by ATM and ATR as well as by CHK1 and CHK2 to stabilize and increase the level of cellular p53 (Shiloh, 2003). As most mutations in DNA occur when a cell with unrepaired damage enters S phase of the cell cycle, DDR checkpoints arrest the progression of cell cycle to allow additional time for excision repair of the damage, or for DNA damage avoidance, or for TLS. Should the checkpoints fail to prevent polymerase stalling, or if the damage is too extensive, cells can undergo apoptosis to eliminate heavily damaged or dysregulated cells.

As cells continually respond to endogenous DNA damage, the adaptive and homeostatic responses have been shown to also be utilized following exposures to DNA-reactive agents at all exposure doses (Noonan et al., 2012; Tentner et al., 2012; Li et al., 2014; Zhang et al., 2015). The fast-acting posttranslational networks, involving signaling ATM, ATR, p38, CHK2, and p53 cascades, are the main contributors to the avoidance of genotoxic outcomes at endogenous and at low exogenous DNA damage load of various classes (Zhang et al., 2014, 2015). However, the transcriptional up-regulation of genes occurred at higher concentrations of bilinear dose–response curves with clear increases in micronuclei formation (Seidel et al., 2004; Zhang et al., 2014, 2015). ATM signaling kinase and p53 tumor suppressor are key players in DDR, but cells can utilize parallel DDR signaling pathways that are independent of ATM and p53 cascades, underscoring the complexity and interconnectedness of biological responses to DNA damage (Hickman and Samson, 1999; Debiak et al., 2004; Noonan et al., 2012).

Taken together, the probability that DNA damage can be converted into a genetic alteration is influenced by the dose–response relationships of various lesion classes, activated pathways, the complex biological interactions between these pathways, the rate of the damage repair, and the fidelity and completeness of the repair. The mechanisms of induction of gene mutations and chromosome alterations discussed in the following sections build upon the assessment of the probability and the mechanistic knowledge of repair versus mis-repair versus non-repair of the different DNA repair and DDR mechanisms.

MECHANISMS OF INDUCTION OF GENETIC ALTERATIONS

Formation of Gene Mutations

Somatic Cells Mutations result in changes to the structure of a gene (Lodish et al., 2000). Gene mutations are considered to be small DNA sequence changes confined to a single gene such as point mutations, which involve alterations in a single base pair that affect the function of only one gene, and small deletions/additions in any DNA region. Larger genomic changes are considered below, under the section "Formation of Chromosomal Alterations." Changes in a single base pair may produce one of three types of mutation: *missense mutation,* which results in a protein with one amino acid substituted for another; *nonsense mutation,* in which a stop codon replaces an amino acid codon, leading to premature termination of translation; and *frameshift mutation,* which causes a change in the reading frame by an addition or deletion of one or a few base pairs (not in multiples of three) in protein-coding regions, leading to pre-mature termination of the protein (Ripley; 1991; Lodish et al., 2000). Base substitutions can be further subdivided as transitions where the change is purine for purine or pyrimidine for pyrimidine, and transversions where the change is purine for pyrimidine and vice versa. Historically, nonsense mutations where the stop codon in the transcribed RNA is UAA are termed as *ochre* mutations, those with UAG codon are called *amber* mutations, and those with UGA are referred to as *opal* mutations. For the discussion of the mechanism of induction of gene mutations and chromosomal alterations, it is necessary to distinguish substances by their general mode of action (MOA). Chemicals that can produce genetic alterations with similar effectiveness in all stages of the cell cycle are called radiomimetic because they act like radiation; the radiomimetic group includes bleomycin, streptonigrin, neocarzinostatin, and 8-ethoxycaffeine. Mutations caused by such chemicals tend to be deletions caused by DNA strand breaks ranging in size from a few bases to multilocus events (Thacker, 1992). As discussed previously, DNA strand breaks are rapidly repaired by multiple repair processes before DNA replication takes place. Therefore, mutations induced by ionizing radiation tend to be the result of errors of DNA repair (Preston, 1992). In contrast, chemicals that produce genetic alterations far more effectively in the S phase of the cell cycle are described as nonradiomimetic. The great majority of chemicals are nonradiomimetic.

Gene mutations can arise in the absence of specific exogenous exposures to radiation and chemicals. The great majority of spontaneous mutations arise from polymerase slippage, DNA biosynthetic errors, and replication errors of an altered template; spontaneous altered template can be a result of oxidative and alkylated damage, or the deamination of bases especially cytosine in DNA/5-methylcytosine at CpG sites resulting in uracil or thymine, respectively, eventually leading to G:C-to-A:T transitions after two rounds of DNA replication (Shinde et al., 2003; Jinks-Robertson and Bhagwat, 2014).

Gene mutations induced by a majority of chemicals and non-ionizing radiations are base substitutions, frameshifts, and small deletions produced by errors of DNA replication on a damaged template. The relative mutation frequency of an adduct will be the outcome of kinetics between its repair and DNA replication, that is, in general terms, the more repair that takes place prior to replication, the lower the mutation frequency for a given amount of induced DNA damage. Furthermore, the nature of an unrepaired adduct dictates its miscoding properties expressed by DNA polymerases during the S phase (Jarabek et al., 2009). Not all DNA adducts are miscoding; small alkyl adducts frequently found at the *N7* position of guanine are not mutagenic and do not block DNA replication progress (Beranek, 1990; Boysen et al., 2009; Swenberg et al., 2011; Philippin et al., 2014). Activation of S phase at a G_1/S cell cycle checkpoints through signaling cascades involving kinases such as ATM, ATR, CHEK1, CHK2, and p53 is an important modulator of these kinetics, as more repair can take place prior to the cell starting/re-starting DNA replication (Mercer, 1998; Giglia-Mari et al., 2011). Finally, error-prone translesion synthesis past

pro-mutagenic lesions can lead to mutations (Fix et al., 2008; Sale, 2013).

Germ Cells Mutations in germ cells are changes to the DNA sequence of sperm or egg that can be inherited by the offspring (Yauk et al., 2015). The mechanism of production of gene mutations in germ cells is basically the same as in somatic cells. It was estimated that a child inherits an average of one de novo mutation per 100×10^6 parental nucleotides (Roach et al., 2010; Conrad et al., 2011). An important consideration for assessing gene mutations induced by chemicals in germ cells is the relationship between exposure and the timing of DNA replication. In the mammalian spermatogonial stem cell, only a small fraction of the 8-day or longer cell cycle is being occupied by the S phase; thus, the probability of DNA repair taking place prior to DNA replication is high. However, for considerations of the genetic risk, the spermatogonial stem cell is present throughout the reproductive lifetime of an individual; each time it divides, it produces a differentiating spermatogonium and a stem cell that can accumulate genetic damage. Differentiating spermatogonia undergo a series of mitotic divisions before entering meiosis, followed by a series of morphological transformation to produce spermatozoa (Clermont, 1972); the late spermatid/spermatozoa stages become DNA repair deficient (Marchetti and Wyrobek, 2005; Olsen et al., 2005). Postmeiotic germ cells are particularly sensitive to mutation induction by nonradiomimetic chemicals, especially following acute exposures (Russell, 2004). The fairly short duration of this stage (approximately 21 days in the mouse) means that their contribution to genetic risk following chronic exposures is quite small. The DNA damage incurred during late spermatid/spermatozoa stages can be repaired post-fertilization using the egg's repair proteins (Marchetti et al., 2007). In contrast, oocyte is resistant to the induction of gene mutations by nonradiomimetic chemicals for which DNA repair is the mode of formation of mutations, and DNA repair occurs in oocytes as there is no further S phase until the zygote (Brewen and Preston, 1982).

The mechanistic aspects of the production of heritable gene mutations in male premeiotic germ cells has recently been considered for monofunctional alkylating chemicals and presented as an adverse outcome pathway (AOP) (Yauk et al., 2015). In general, AOPs describe a simplified series of key events (KEs) along the biological organization of organisms that lead to an adverse health or population effects (Villeneuve et al., 2014a, 2014b). An AOP links a molecular initiating event (MIE) to an adverse outcome (AO) through intermediate KEs. The tailored Bradford-Hill considerations for key event relationships (KERs) and evidence evaluation of the essentiality of KEs to AO are systematically assessed under this framework. The AOP for alkylation of DNA in male premeiotic germ cells leading to heritable mutations is presented in Fig. 9-5. The MIE for this AOP has been designated as the alkylation of DNA in male premeiotic germ cells. This MIE is followed by the KE1: insufficient or incorrect DNA repair in male premeiotic germ cells, and KE2: increased mutations in male premeiotic germ cells. Mutations that do not impair spermatogenesis persist and eventually are present in mature sperm can be measured with in vivo transgenic rodent mutation (OECD TG 488, 2013) assay or mutations in simple tandem repeat DNA sequences (Yauk, 2004). Eventually, these series of KEs lead to an adverse outcome (AO) of increased heritable mutations in the offspring. Inherited mutations in the offspring can lead to embryonic or fetal death, or be transmitted to the offspring and cause phenotypic outcomes; thus, heritable mutation is an important regulatory endpoint used by the agencies around the world for risk assessment and regulatory purposes (Vinken, 2013; Yauk et al., 2015). The overall AOP is generally accepted as dogma with strong essentiality of its KEs and KERs as well as strong biological plausibility without notable inconsistencies and uncertainties.

Formation of Chromosomal Alterations

Somatic Cells

Structural Chromosome Aberrations Large-scale changes in chromosome structure can affect the functioning of numerous genes, resulting in major phenotypic consequences (Lodish et al., 2000). These chromosomal mutations, or abnormalities, can involve deletion or insertion of several contiguous genes, inversion of genes on a chromosome, or the exchange of large segments of DNA between nonhomologous chromosomes. Chromosome aberrations induced by ionizing radiations are generally formed by errors of DNA repair, whereas those produced by nonradiomimetic chemicals are generally formed by errors of DNA replication on a damaged DNA template.

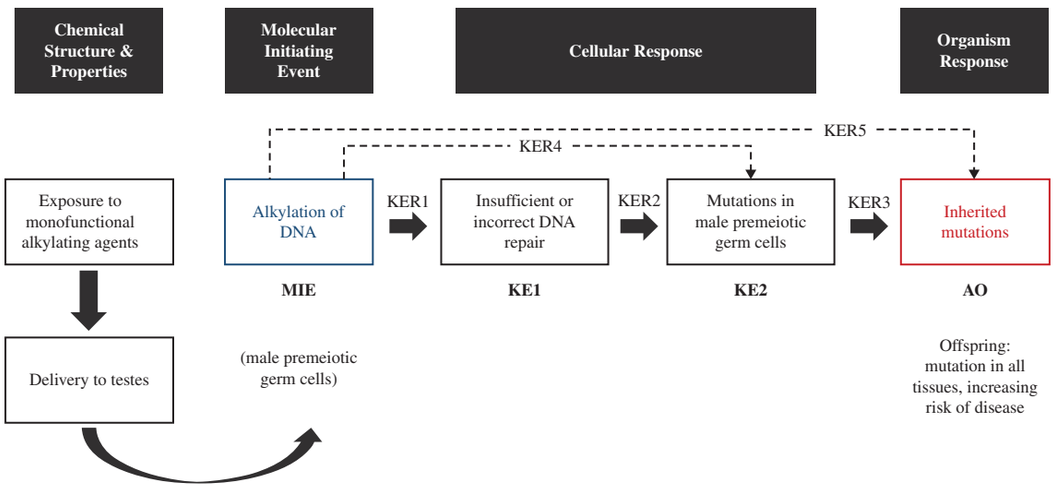

Figure 9-5. *Flow diagram of the alkylation of DNA in male premeiotic germ cells leading to heritable mutations AOP depicting the MIE, KEs, AO, and KERs.* (Reproduced with permission from Yauk et al., 2015.)

The DNA repair errors that lead to the formation of chromosome aberrations following ionizing radiation (and radiomimetic chemical) exposure arise from misligation of double-strand breaks or interaction of coincidentally repairing regions during excision repair of damaged bases. The overall kinetics and fidelity of DNA repair influence the sensitivity of cells to the induction of chromosomal aberrations produced by misrepair. The broad outcomes of misrepair are that incorrect rejoining of chromosomal pieces during repair leads to chromosomal exchanges within (e.g., inversions and interstitial deletions) and between (e.g., dicentrics and reciprocal translocations) chromosomes. Failure to rejoin double-strand breaks or to complete the repair of other types of DNA damage leads to terminal deletions.

Acentric fragments arise from interstitial deletions, terminal deletions, and the formation of dicentric chromosomes and rings. The failure to incorporate an acentric fragment into a daughter nucleus at anaphase/telophase, or the failure of a whole chromosome to segregate at anaphase to the cellular poles, can result in the formation of a membrane-bound micronucleus that resides in the cytoplasm.

Errors of DNA replication on a damaged template can lead to a variety of chromosomal alterations. The majority of these involve deletion or exchange of individual chromatids (chromatid-type aberrations). Thus, nonradiomimetic chemicals induce only chromatid-type aberrations, whereas radiation and radiomimetic chemicals induce chromatid-type aberrations in the S and G_2 phases of the cell cycle, but chromosome-type aberrations affecting both chromatids in G_1. The reason for this latter observation is that the G_1 (or G_0) chromosome behaves as a single DNA molecule and aberrations formed in it will be replicated in the S phase and will involve both chromatids. This distinction is important for considerations of outcome of the aberrations and the probability of an effect on cells because for chromatid-type aberrations, one chromatid remains intact and genetically unaltered, in contrast to chromosome-type aberrations in which both chromatids are damaged (Preston et al., 1995).

Numerical Chromosome Changes Numerical changes (e.g., monosomies, trisomies, and ploidy changes) can arise from errors in chromosomal segregation. The complexity of the control and the mechanics of the mitotic process means that alteration of various cellular components can result in failure to segregate the sister chromatids to separate daughter cells or in failure to segregate a chromosome to either pole (Bickel and Orr-Weaver, 1996; Preston, 1996; Hunt, 2006). The mechanisms underlying chromosomal loss are pertinent to those involved in the formation of micronuclei. Aneuploidy is a known cause of human disease and represents a major cause of infertility, pregnancy failure, and serious genetic disorders in the offspring.

A limited set of chemicals has been demonstrated to cause aneuploidy through interaction with components of the structures that facilitate chromosome movement (Preston, 1996; Aardema et al., 1998). These include benomyl, griseofulvin, nocodazole, colchicine, colecemid, vinblastine, and paclitaxel. These chemicals affect tubulin polymerization or spindle microtubule stability. A group of small molecule drugs that are targeted to inhibit Aurora kinases, a family of serine/threonine kinases important for proper attachment of microtubules at spindle assembly during cell division, have been shown to induce aneuploidy (Gollapudi et al., 2014; Bavetsias and Linardopoulos, 2015). To date, other mechanisms of aneuploidy induction by chemicals have not been firmly identified.

Germ Cells The formation of chromosomal alterations in germ cells is basically the same as that for somatic cells, namely, via misrepair for ionizing radiations and radiomimetic chemicals for treatments in G_1 and G_2, and by errors of replication for all radiations and chemicals for DNA damage present during the S phase.

The types of aberrations formed in germ cells are the same as those formed in somatic cells (e.g., deletions, inversions, translocations), although their appearance in diplotene/diakinesis of meiosis I, where analysis is frequently conducted, is rather different because of the homologous chromosome pairing that takes place in meiotic cells (Léonard, 1973). The specific segregation of chromosomes during meiosis influences the probability of recovery of an aberration, particularly a reciprocal translocation, in the offspring of a treated parent (Preston et al., 1995).

An adverse outcome pathway (AOP) for chemical binding to tubulin in oocytes leading to aneuploid offspring has been developed and published (Marchetti et al., 2016). Colchicine, a prototypical chemical that binds to tubulin and causes microtubule depolymerization has been used to develop the AOP. In this AOP specific to female germ cells exposed during the periovulation period, chemicals that bind to tubulin (MIE) cause microtubule depolymerization (KE1) resulting in spindle disorganization (KE2) followed by altered chromosome alignment and segregation (KE3) and the generation of aneuploid oocytes (KE4), ultimately leading to an increased incidence of aneuploidy syndromes in the offspring (AO). The available evidence suggests that the MIE and KEs are conserved across species and would be relevant for human oocytes. The development of AOPs related to mutagenicity in germ cells is expected to aid the identification of potential hazards to germ cell genomic integrity and support regulatory efforts to protect population health (Marchetti et al., 2016).

ASSAYS FOR DETECTING GENETIC ALTERATIONS

Introduction to Assay Design

Genetic toxicology assays are used to identify germ cell mutagens, somatic cell mutagens, and potential carcinogens. These assays can detect diverse kinds of genetic alterations (e.g., gene mutations, chromosome aberrations, and aneuploidy) that are relevant to the production of adverse human health outcomes. Over the last three decades, hundreds of chemicals and complex mixtures have been evaluated for genotoxic effects. Genetic toxicology assays serve two interrelated but distinct purposes in the toxicologic evaluation of chemicals: (1) identifying mutagens for purposes of hazard identification and (2) characterizing dose–response relationships and mutagenic mechanisms, both of which contribute to an understanding of genetic and carcinogenic risks.

A common experience when surveying the genetic toxicology literature is encountering a bewildering array of assays in viruses, bacteria, fungi, cultured mammalian cells, plants, insects, and mammals. More than 200 assays for mutagens have been proposed, and useful information has been obtained from many of them. Although most genetic toxicology testing and evaluation relies on relatively few assays, data from relatively obscure assays can sometimes contribute to a judgment about the genetic activity of a compound.

Table 9-1 lists key assays that have a prominent place in genetic toxicology. Table 9-2 is a more comprehensive list that provides literature citations to many of the assays that one might encounter in the genetic toxicology literature. Even this extensive table is not exhaustive, in that it emphasizes methods in applied genetic toxicology and not those assays whose use has been largely restricted to studies of mutational mechanisms. The commonly used assays rely on phenotypic effects as indicators of gene mutations or small deletions and on cytological methods for observing gross chromosomal damage. Detailed information on assay design, testing data, controls, sample sizes, and other factors in effective testing is found in the references cited.

Table 9-1

Principal Assays in Genetic Toxicology

BATTERY	ASSAY TYPE	ASSAY DESCRIPTION
Current strategies for genotoxicity testing in vitro	Bacterial reverse mutation test (Ames test) for gene mutations	At least five amino-acid requiring strains of *Salmonella typhimurium* and *Escherichia coli* are used to detect point mutations (base-pair substitution, addition, or deletion of one or a few DNA base pairs) that restore the functional capability of the bacteria to synthesize an essential amino acid.
	Chromosomal damage and aneuploidy in mammalian cell cultures	In vitro mammalian chromosomal aberration test in somatic cells. A micronucleus assay detecting both clastogenicity and aneugenicity.
	Gene mutations in mammalian cell cultures	Forward mutation assay at *tk* locus of mouse lymphoma L5178Y cells or at the *hprt* locus of cell lines derived from Chinese hamster or human lymphoblastoid TK6 cells.
Current strategies for genotoxicity testing in vivo	An assay for the assessment of cytogenetic damage in rodent bone marrow cells	A micronucleus assay is preferred since it detects both clastogenicity and aneugenicity. A mammalian in vivo chromosome aberration test detects structural chromosome aberrations in rodent bone marrow cells.
	Gene-mutation assays in rodent somatic cells	Transgenic *lacI*, *lacZ*, *cII* loci of Big Blue®, Muta™ Mouse, etc., detect mutations in vivo in any tissue of choice.
	Genotoxicity assay for detection of DNA damage and repair	In vivo comet assay (single cell gel electrophoresis assay) recommended for follow-up testing of positive in vitro findings. Also useful as a tool for the evaluation of local genotoxicity, especially for organs/cell types which cannot easily be evaluated with other standard tests.
Other genetic toxicity assays	Assays for gene mutations	Gene-mutation assays in rodent somatic cells, e.g., *Pig-a*.
		Saccharomyces cerevisiae Gene Mutation Assay (OECD guideline deleted).
		Drosophila sex-linked recessive lethal assay (OECD guideline deleted).
	Genotoxicity assays	Sister chromatid exchange assay detects reciprocal exchanges of DNA segments between two sister chromatids of a duplicating chromosome.
		Unscheduled DNA synthesis test with mammalian liver cells detects DNA synthesis after excision repair of damaged DNA.
		Mitotic recombination assay in *Saccharomyces cerevisiae* (OECD guideline deleted).
	Mammalian germ cell assays	Mouse specific-locus tests.
		Cytogenetic analysis and heritable translocation assays.
		DNA damage and repair in rodent germ cells.
		Mutation analysis in germ cells of transgenic rodents.
		Mutation analysis in tandem-repeat loci in mice.

OECD guideline deletion means that no new testing shall be initiated using any deleted Test Guideline, but the results generated shall continue to be accepted in the regulatory settings and for weight-of-evidence assessments.

Some assays for gene mutations detect forward mutations whereas others detect reversion. Forward mutations, such as those detected in the *thymidine kinase* (*tk*) gene in the widely used assay in mouse lymphoma cells (Clements, 2000; Wang et al., 2009; Schisler et al., 2013), are genetic alterations in a wild type gene that are detected by a change in phenotype caused by the alteration or loss of gene function. In contrast, reversion mutations are those that restore gene function in a mutant, such as the histidine revertants detected in the Ames assay in *Salmonella* (Ames et al., 1975; Mortelmans and Zeiger, 2000; Claxton et al., 2010). Thus, a back mutation or reversion that restores gene function in a mutant brings about a return to the wild type phenotype. In principle, forward-mutation assays should respond to a broad spectrum of mutagens because any mutation that interferes with gene expression should confer the detectable phenotype. A reversion assay might be expected to have a more restricted mutational response because only mutations that correct or compensate for the specific mutation in a particular mutant will be detected. In fact, some reversion assays respond to a broader spectrum of mutational changes than one might expect because mutations at a site other than that of the original mutation, either within the test gene or in a different gene (i.e., a suppressor mutation), can sometimes confer the selected phenotype. Both forward mutation assays and reversion assays are used extensively in genetic toxicology.

The simplest gene mutation assays rely on selection techniques to detect mutations. A selection technique is a means of imposing experimental conditions under which only cells or organisms that have undergone mutation can grow. For example, only cells that have a mutation in the *tk* gene can grow in medium containing the inhibitory chemical trifluorothymidine (Seifried et al., 2006; Wang et al., 2009; Schisler et al., 2013). Selection techniques greatly facilitate the identification of rare cells that have experienced mutation among the many cells that have not. Forward mutations (Clements, 2000; Vlasakova et al., 2005) and reversions (Josephy, 2000; Mortelmans and Riccio, 2000; Mortelmans and Zeiger, 2000; Kamber et al., 2009) can both be detected by selection techniques in microorganisms and cultured mammalian cells. Due to their speed, low cost, and ease of detecting events that occur at low frequency (i.e., mutation), assays in microorganisms and cell cultures have figured prominently in genetic toxicology.

Studying mutagenesis in intact animals requires assays of more complex design than the simple selection methods used in

Table 9-2

Overview of Genetic Toxicology Assays

ASSAYS	SELECTED LITERATURE CITATIONS
I. Prediction of genotoxicity	
A. Interpretation of chemical structure	
Structural alerts to genotoxicity	Ashby (1994), Ashby and Tennant (1991), Ashby and Paton (1993)
B. In silico predictive models	
Computational and structural programs: MCASE, TOPKAT, DEREK	Snyder et al. (2004), Snyder and Smith (2005), Snyder (2009), Mahadevan et al. (2011)
Quantitative structure–activity relationship (QSAR) modeling	Votano et al. (2004), Snyder and Smith (2005), Mahadevan et al. (2011)
II. DNA damage and repair assays	
A. Direct detection of DNA damage:	
Alkaline elution assays for DNA strand breakage in hepatocytes	Storer et al. (1996), Gealy et al. (2007)
Comet assay (single-cell gel electrophoresis) for DNA strand breakage	Fairbairn et al. (1995), Singh (2000), Tice et al. (2000), Collins (2004), Olive (2009)
CometChip	Weingeist et al. (2013), Ge et al. (2014)
Nonmammalian comets in ecotoxicology	Cotelle and Férard (1999), Lee and Steinert (2003), Jha (2004)
Assays for chemical adducts in DNA	Phillips et al. (2000), Farmer and Singh (2008), Himmelstein et al. (2009)
B. DNA repair, recombination, and genotoxic stress responses as indicators of damage:	
Differential killing of repair-deficient and wild type bacteria	Takigami et al. (2002)
Induction of the bacterial SOS system	Quillardet and Hofnung (1993), Yasunaga et al. (2004), Oda et al. (2009)
"Green Screen" for *GADD45a* gene induction in TK6 human cells	Hastwell et al. (2009), Jagger et al. (2009), Hughes et al. (2012)
Unscheduled DNA synthesis (UDS) in isolated rat hepatocytes or rodents in vivo	Madle et al. (1994), McQueen and Williams (1987), Butterworth et al. (1987)
Induction of mitotic recombination	Zimmermann (1992), Hoffmann (1994), Vogel and Nivard (2000), Turner et al. (2003), Reliene et al. (2007)
III. Prokaryote gene-mutation assays	
A. Bacterial reverse mutation assays:	
Salmonella/mammalian microsome assay (Ames test)	Ames et al. (1975), Kier et al. (1986), Maron and Ames (1983), Gatehouse et al. (1994), Mortelmans and Zeiger (2000), Seifried et al. (2006), Claxton et al. (2010)
E. coli WP2 tryptophan reversion assay	Gatehouse et al. (1994), Mortelmans and Riccio (2000)
Salmonella-specific base-pair substitution assay (Ames II assay)	Gee et al. (1994), Kamber et al. (2009)
E. coli lacZ-specific reversion assay	Cupples and Miller (1989), Cupples et al. (1990), Josephy (2000), Hoffmann et al. (2003)
B. Bacterial forward mutation assays:	
E. coli lacI assay	Calos and Miller (1981), Halliday and Glickman (1991)
Resistance to toxic metabolites or analogs in *Salmonella*	Jurado et al. (1994), Vlasakova et al. (2005)
IV. Assays in nonmammalian eukaryotes:	
A. Fungal assays:	
Forward mutations, reversion, and small deletions	Zimmermann et al. (1984), Crouse (2000)
Mitotic crossing over, gene conversion, and homology-mediated deletions in yeast	Zimmermann et al. (1984), Zimmermann (1992), Howlett and Schiestl (2000), Daigaku et al. (2004), Freeman and Hoffmann (2007)
Genetic detection of mitotic and meiotic aneuploidy in yeast	Zimmermann et al. (1984), Aardema et al. (1998), Howlett and Schiestl (2000), Nunoshiba et al. (2007)
B. Plant assays:	
Gene mutations affecting chlorophyll in seedlings, the *waxy* locus in pollen, or *Tradescantia* stamen-hair color	Ma et al. (2005), Grant and Owens (2006)
Chromosome aberrations and micronuclei in mitotic and meiotic cells of corn, *Tradescantia*, and other plants	Ma et al. (2005), Grant and Owens (2006), Misík et al. (2011)

(*continued*)

ASSAYS	SELECTED LITERATURE CITATIONS
C. *Drosophila* assays:	
Sex-linked recessive lethal test in germ cells	Lee et al. (1983), Mason et al. (1987), Vogel et al. (1999)
Heritable translocation assays	Mason et al. (1987), Vogel et al. (1999)
Mitotic recombination and LOH in eyes or wings	Vogel et al. (1999), Vogel and Nivard (2000)
V. Mammalian gene-mutation assays	
A. In vitro assays for forward mutations:	
tk mutations in mouse lymphoma or human cells	Clements (2000), Seifried et al. (2006), Wang et al. (2009), Moore et al. (2011), Schisler et al. (2013)
hprt or *xprt* mutations in Chinese hamster or human cells	Li et al. (1988), DeMarini et al. (1989), Parry et al. (2005)
CD59 mutations in CHO-human hybrid A_L cells	Zhou et al. (2006), Ross et al. (2007)
B. In vivo assays for gene mutations in somatic cells:	
Mouse spot test (somatic cell specific-locus test)	Styles and Penman (1985), Lambert et al. (2005)
hprt mutations (6-thioguanine-resistance) in rodent lymphocytes	Cariello and Skopek (1993), Casciano et al. (1999), Lambert et al., 2005
Pig-a mutations (immunological detection of mutations blocking glycosylphosphatidylinositol synthesis)	Dobrovolsky et al. (2010), Miura et al. (2011), Dobo et al. (2011), Gollapudi et al. (2015)
C. Transgenic assays:	
Mutations in the bacterial *lacI* gene in Big Blue® mice and rats	Lambert et al. (2005), Singer et al. (2006)
Mutations in the bacterial *lacZ* gene in the Muta™ Mouse	Lambert et al. (2005), Singer et al. (2006)
Mutations in the phage *cII* gene in *lacI* or *lacZ* transgenic mice	Shane et al. (2000), Swiger (2001), Lambert et al. (2005)
Point mutations and deletions in the *lacZ* plasmid mouse	Lambert et al. (2005), Singer et al. (2006)
Point mutations and deletions in *gpt delta* mice and rats	Okada et al. (1999), Lambert et al. (2005), Nohmi (2016)
Forward mutations and reversions in ΦX174 transgenic mice	Valentine et al. (2010)
Inversions and deletions arising in pKZ1 mice by intrachromosomal recombination	Sykes et al. (2006)
VI. Mammalian cytogenetic assays	
A. Chromosome aberrations:	
Metaphase analysis in cultured Chinese hamster or human cells	Ishidate et al. (1988), Kirkland et al. (1990), Galloway et al. (1994), Galloway (2000), Corvi et al. (2008), Galloway et al. (2011)
Metaphase analysis of rodent bone marrow or lymphocytes in vivo	Preston et al. (1981), Kirkland et al. (1990), Tice et al. (1994)
Chromosome painting and other FISH applications in vitro and in vivo	Tucker et al. (1993b, 2005), Paccierotti and Sgura (2008)
B. Micronuclei:	
Cytokinesis-block micronucleus assay in human lymphocytes	Fenech et al. (2003), Corvi et al. (2008), Fenech (2008), Fenech et al. (2011a, 2011b)
Micronucleus assay in mammalian cell lines	Kirsch-Volders et al. (2003), Corvi et al. (2008), Galloway et al. (2011)
In vivo micronucleus assay in rodent bone marrow or blood	Krishna and Hayashi (2000), Hayashi et al. (2007), Tweats et al. (2007), Dertinger et al. (2011)
In vivo micronucleus assay in tissues other than marrow or blood	Hayashi et al. (2007), Coffing et al. (2011), Morita et al. (2011)
C. Sister chromatid exchange:	
SCE in human cells or Chinese hamster cells	Tucker et al. (1993a), Wilson and Thompson (2007)
SCE in rodent tissues, especially bone marrow	Tucker et al. (1993a)
D. Aneuploidy in mitotic cells:	
Hyperploidy detected by chromosome counting or FISH in cell cultures or bone marrow	Galloway and Ivett (1986), Natarajan (1993), Aardema et al. (1998), Paccierotti and Sgura (2008)
Micronucleus assay with centromere/kinetochore labeling in cell cultures	Lynch and Parry (1993), Natarajan (1993), Aardema et al. (1998), Fenech (2008), Paccierotti and Sgura (2008)

(*continued*)

ASSAYS	SELECTED LITERATURE CITATIONS
Altered parameters in flow-cytometric detection of micronuclei in CHO cells	Bryce et al. (2011)
Mouse bone marrow micronucleus assay with centromere labeling	Adler (1993), Aardema et al. (1998), Krishna and Hayashi (2000)
VII. Germ cell mutagenesis	
A. Measurement of DNA damage	
Molecular dosimetry based on mutagen adducts in reproductive cells	Russell and Shelby (1985), Olsen et al. (2010), Verhofsrad et al. (2011)
UDS in rodent germ cells	Bentley et al. (1994), Sotomayor and Sega (2000)
Alkaline elution assays for DNA strand breaks in rodent testes	Bentley et al. (1994)
Comet assay in sperm and gonadal tissue	Speit et al. (2009)
B. Gene mutations	
Mouse specific-locus test for gene mutations and deletions	Russell et al. (1981), Ehling (1991), Russell and Russell (1992), Favor (1999), Russell (2004), Singer et al. (2006)
Mouse electrophoretic specific-locus test	Lewis (1991)
Dominant mutations causing mouse skeletal defects or cataracts	Ehling (1991), Selby et al. (2004)
ESTR assay in mice	Yauk (2004), Dubrova (2005), Singer et al. (2006), Somers (2006)
Germ cell mutations in transgenic assays	Lambert et al. (2005), Singer et al. (2006)
C. Chromosomal aberrations	
Cytogenetic analysis of oocytes, spermatogonia, spermatocytes, or zygotes	Kirkland et al. (1990), Tease (1992), Russo (2000), Marchetti et al. (2001)
Direct detection in sperm by FISH	Marchetti et al. (2006, 2008)
Micronuclei in mouse spermatids	Russo (2000), Hayashi et al. (2007)
Mouse heritable translocation test	Russell and Shelby (1985), Singer et al. (2006)
D. Dominant lethal mutations	
Mouse or rat dominant lethal assay	Adler et al. (1994), Singer et al. (2006)
E. Aneuploidy	
Cytogenetic analysis for aneuploidy arising by nondisjunction	Allen et al. (1986), Adler (1993), Adler et al. (1994), Aardema et al. (1998), Russo (2000), Marchetti et al. (2001)
Sex chromosome loss test for nondisjunction or breakage	Russell and Shelby (1985)
Micronucleus assay in spermatids with centromere labeling	Aardema et al. (1998)
FISH with probes for specific chromosomes in sperm	Russo (2000), Marchetti et al. (2006, 2008)

microorganisms and cultured cells. Genetic toxicology assays therefore range from inexpensive short-term tests (Zeiger, 2010) that can be performed in a few days to complicated assays for mutations in mammalian germ cells (Favor, 1999; Russell, 2004; Singer et al., 2006). Even in multicellular organisms, there has been an emphasis on designing assays that detect mutations with great efficiency (Casciano et al., 1999; Vogel et al., 1999; Lambert et al., 2005; Dobrovolsky et al., 2010). Nevertheless, there remains a gradation in which an increase in relevance for human risk entails more elaborate and costly tests (Table 9-2). The most expensive mammalian tests are typically reserved for chemicals of special importance in basic research or risk assessment, whereas the simpler assays can be applied more broadly.

Cytogenetic assays differ in design from typical gene mutation assays because of their reliance on cytological rather than genetic methods. The goal in cytogenetic methods is the unequivocal visual recognition of cells that have experienced genetic damage. The alterations measured include chromosome aberrations (Preston et al., 1981; Ishidate et al., 1988; Corvi et al., 2008), micronuclei (Hayashi et al., 2007; Corvi et al., 2008; Fenech et al., 2011a, 2011b), sister chromatid exchanges (SCEs; Tucker et al., 1993a; Wilson and Thompson, 2007), and changes in chromosome number (Aardema et al., 1998; Paccierotti and Sgura, 2008). The latter include ploidy changes (e.g., polyploid cells) and aneuploidy, in which one or a few chromosomes have been gained (i.e., hyperploidy) or lost (i.e., hypoploidy) relative to the normal chromosome number. Aneuploidy is of great interest because of its implications for human health, but assays for aneuploidy are not yet as refined or systematically applied as those for other classes of chromosomal alterations. The biological and toxicological significance of SCEs is largely unknown and as such tests for SCE induction are no longer included as part of genotoxicity assessment.

In all mutagenicity testing, one must be aware of possible sources of error. Factors to consider in the application of mutagenicity assays are the choice of suitable organisms and growth conditions, appropriate monitoring of genotypes and phenotypes,

effective experimental design and treatment conditions, inclusion of proper positive and negative controls, and sound methods of data analysis. The articles cited in Table 9-2 discuss these aspects of genetic toxicology testing. In addition, the publication by Lorge et al. (2016) provides guidance on good cell culture practices in the conduct of genetic toxicology assays using mammalian cell cultures.

Many substances that are not themselves mutagenic or carcinogenic can be activated into mutagens and carcinogens by metabolism (Guengerich, 2001; Malling, 2004). Such chemicals are called promutagens and procarcinogens. Since microorganisms and mammalian cell cultures lack many of the metabolic capabilities of intact mammals, provision must be made for metabolic activation in order to detect promutagens in many genetic assays. Incorporating an in vitro metabolic activation system derived from a mammalian tissue homogenate is the most common means of adding metabolic activation to microbial or cell culture assays (Malling and Frantz, 1973; Ames et al., 1975; Clements, 2000; Malling, 2004; Cox et al., 2016). For example, the promutagens dimethylnitrosamine and benzo[*a*]pyrene are not themselves mutagenic in bacteria, but they are mutagenic in bacterial assays if the bacteria are treated with the promutagen in the presence of a homogenate from mammalian liver.

The most widely used metabolic activation system in microbial and cell culture assays is a postmitochondrial supernatant from a rat liver homogenate, along with appropriate buffers and cofactors (Maron and Ames, 1983; Kirkland et al., 1990). The standard liver metabolic activation system is called an S9 mixture, designating a supernatant from centrifugation at 9000 g (Malling and Frantz, 1973; Maron and Ames, 1983). The S9 subcellular fraction contains microsomes and cytosol with microsomes containing enzymes necessary for Phase I metabolism (e.g., cytochrome P450s) and cytosol containing the enzymes involved in Phase II metabolism. Most of the short-term assays in Table 9-2 require exogenous metabolic activation to detect promutagens. Exceptions are assays in intact mammals and a few simpler assays that have a high level of endogenous cytochrome P450 metabolism, such as the detection of UDS or DNA strand breakage in cultured hepatocytes (Madle et al., 1994; Gealy et al., 2007).

Rat liver S9, usually prepared following induction with Aroclor-1254 (a mixture of polychlorinated biphenyls) or phenobarbital/β-naphthoflavone, provides a broad assemblage of metabolic reactions, but they are not necessarily the same as those of hepatic metabolism in an intact animal (Richardson et al., 2016). Metabolic activation systems based on homogenates from mice, guinea pigs, hamsters, or monkeys and preparations from organs other than liver have found some use in mutagenicity testing (Mortelmans and Zeiger, 2000). In some cases, these systems detect mutagenicity more efficiently than rat liver S9. However, like a homogenate from rat liver, these systems may differ from the species or organs of their origin. Therefore, alternative metabolic activation systems tend to be more useful if chosen for mechanistic reasons rather than simply testing another species or organ. Such systems include the use of intact hepatocytes (Madle et al., 1994; Storer et al., 1996; Gealy et al., 2007) to preserve the cellular compartmentalization of reactions; an in vitro system that can carry out the reduction reactions needed to detect the activity of substances whose mutagenicity requires reductive metabolism, such as some azo compounds (Mortelmans and Zeiger, 2000; Seifried et al., 2006); and the use of mammalian cells or bacteria engineered to express foreign genes that encode enzymes of metabolic activation (Sawada and Kamataki, 1998; Crespi and Miller, 1999; Josephy, 2000, 2002; Oda et al., 2009).

Besides metabolic activation, some chemicals are subject to photochemical activation. The genotoxicity of such chemicals depends on the chemical being irradiated with ultraviolet or visible light. Many of the assays listed in Table 9-2, including gene-mutation assays in bacteria and cultured mammalian cells, cytogenetic assays, and the comet assay, have been adapted so that they can measure photogenotoxic effects (Brendler-Schwaab et al., 2004; Lynch et al., 2011).

Genes encoding enzymes of xenobiotic metabolism have been incorporated by recombinant DNA technology into microorganisms or cell cultures to expand their capacity for metabolic activation. The genes incorporated into bacteria may be derived from other bacteria or from humans (Josephy, 2002; Oda et al., 2009). For example, bacterial genes that cause overexpression of *N*-acetyltransferase enhance the sensitivity of the bacteria to the mutagenicity of aromatic amines or nitroarenes (Josephy, 2002). The expression of human cytochrome P450 enzymes in *Salmonella* tester strains from the Ames assay (Josephy 2002; Yamazaki et al., 2004), a *Salmonella* SOS-induction assay (Oda et al., 2009), or *E. coli* strains of the *lacZ* reversion assay (Josephy, 2000) permits the activation of promutagens like 2-aminoanthracene and 2-aminofluorene without a S9 mixture. Mammalian cell lines have also been genetically engineered to express human Phase-I and Phase-II enzymes, including those catalyzing reactions of metabolic activation (Sawada and Kamataki, 1998; Chevereau et al., 2017). Many cell lines stably expressing a single form of P450 have been established. Mutagenesis can be measured through such endpoints as *HPRT* mutations, cytogenetic alterations, and γH2AX, and the cells are well suited to analyzing the contribution of different enzymes to the activation of promutagens (Crespi and Miller, 1999; Chevereau et al., 2017).

Metabolic activation is so central to genetic toxicology that all mutagenicity testing programs must provide for it in the choice of assays and procedures. Despite their usefulness, in vitro metabolic activation systems, however well refined, cannot mimic mammalian metabolism perfectly. There are differences among tissues in reactions that activate or inactivate foreign compounds, and organisms of the normal flora of the intestines can contribute to metabolism in intact mammals. Chemicals that induce enzyme systems or otherwise alter the physiological state can also modify the metabolism of toxicants, and the balance between activation and detoxification reactions in vitro may differ from that found in vivo.

Structural Alerts and In Silico Assays

The first indication that a chemical is a mutagen often lies in chemical structure. Potential electrophilic sites in a molecule serve as an alert to possible mutagenicity and carcinogenicity because such sites confer reactivity with nucleophilic sites in DNA (Miller and Miller, 1981; Tennant and Ashby, 1991; Snyder et al., 2004; Votano et al., 2004; Snyder and Smith, 2005). In general, genotoxic carcinogens typically are either electrophiles or can be activated to electrophilic reactive intermediates (pro-electrophiles). These compounds form covalent adducts with most of the cellular macromolecules such as DNA, RNA, or proteins at the nucleophilic centers with electron-rich heteroatoms S, O, or N (Plošnik et al., 2016). The understanding of the mechanisms of action through which electrophiles react with biological nucleophiles is based on the classical chemical reactions (S_N1, S_N1, acylation, Schiff base formation, Michael addition, and S_NAr) between electron-rich and electron-deficient centers (Plošnik et al., 2016). Strong electrophiles (e.g., nitroso compounds, epoxides, α,β- unsaturated aldehydes, *N*-sulphonyloxy-*N*-methyl-4- aminoazobenzene,

N-sulphonyloxy-*N*-acetyl-2-aminofluorene, and *N*-hydroxy-2-aminofluorene) are small, poorly polarized molecules, and their electron deficiency shows as positive electron charge. Soft electrophiles (e.g., safrole, estragole, *N*-methylol-4-aminoazobenzene) are usually large, highly polarized molecules, and their electron deficiency spreads all over the molecule (Plošnik et al., 2016).

Computer-based systems for predicting genotoxicity based on chemical structure properties are sometimes called in silico assays. These assays include computational and structural programs (Snyder and Smith, 2005; Snyder, 2009; Knudsen et al., 2011; Mahadevan et al., 2011) and the modeling of quantitative structure–activity relationships or (Q)SARs (Votano et al., 2004; Snyder and Smith, 2005; Mahadevan et al., 2011). The electrophilic theory of genotoxic carcinogenicity has led to two main (Q)SAR approaches for modeling genotoxic chemicals: (a) to identify the electrophilic functional groups or substructures, that is, to develop SAR models based on structural alerts; and (b) to find molecular descriptors that can be quantitatively related to the activity of the chemicals, that is, to develop (Q)SARs (Serafimova et al., 2010).

Structural alerts in combination with critical interpretation are a valuable initial adjunct to mutagenicity testing within the integrated approaches for testing and assessment of chemicals (Tennant and Ashby, 1991; Ashby and Paton, 1993). Although there is much skepticism that such approaches can replace biological testing, they hold promise of improving the efficiency of integrated testing strategies and reducing current levels of animal use (Guha, 2011; Dearfield et al., 2017; Wichard, 2017). The most commonly modeled endpoint for genotoxicity has been the Ames mutagenicity assay. The accuracy of Ames mutagenicity prediction is typically around 70% to 75% (Serafimova et al., 2010). (Q)SAR predictions should be interpreted by an expert with knowledge of the endpoint, the strengths and limitations of the specific model applied, the applicability domain of the model, and the reliability of prediction for the chemical of interest (Serafimova et al., 2010). Moreover, computational approaches should not be based on stand-alone basis, but on a weight-of-evidence approach including information from all available sources such as read across and in vitro test methods (Serafimova et al., 2010).

DNA Damage and Repair Assays

Some assays measure DNA damage itself, rather than mutational consequences of DNA damage. These assays belong to the category of "indicator assays" and the effects measured in these assays may or may not lead to mutational consequence. Damage to DNA may be induced directly, through such indicators as chemical adducts or strand breaks in DNA, or indirectly, through the measurement of biological repair processes. Adducts in DNA are detected by ^{32}P-postlabeling, high-performance liquid chromatography (HPLC), fluorescence-based methods, mass spectrometry, immunological methods using antibodies against specific adducts, isotope-labeled DNA binding, and electrochemical detection (Phillips et al., 2000; Farmer and Singh, 2008; Himmelstein et al., 2009). The ^{32}P-postlabeling method is highly versatile, in that it is sensitive and can be applied to diverse mutagens, but it may fall short of other methods for quantitative accuracy (Farmer and Singh, 2008). Through a combination of methods, many classes of adducts, including those of such environmentally widespread compounds as polynuclear aromatic hydrocarbons, can be detected. The measurement of adducts after human chemical exposures has proven useful in human monitoring, molecular dosimetry, and risk assessment (Phillips et al., 2000; Farmer and Singh, 2008; Himmelstein et al., 2009). Adducts in somatic cells are relevant to carcinogenesis (Himmelstein et al., 2009), whereas those in reproductive cells permit molecular dosimetry for germ cell mutagenesis (Olsen et al., 2010; Verhofsrad et al., 2011; Yauk et al., 2015).

DNA strand breakage can be measured by alkaline elution (Storer et al., 1996; Gealy et al., 2007) and electrophoretic methods. Single-cell gel electrophoresis, also called the comet assay, is a widely used, rapid method of measuring DNA damage (Fairbairn et al., 1995; Singh, 2000; Tice et al., 2000; Collins, 2004; Olive, 2009; Speit et al., 2015; Glei et al., 2016; Collins et al., 2017). In this assay, cells are incorporated into agarose on slides, lysed so as to liberate their DNA, and subjected to electrophoresis typically under alkaline conditions (pH >13) to allow detection of DNA double-strand breaks, single-strand breaks, alkali-labile sites, DNA-DNA/DNA-protein cross-linking, and incomplete excision repair sites (Fairbairn et al., 1995; Singh, 2000; Tice et al., 2000; Pu et al., 2015). The DNA is stained with a fluorescent dye for observation and image analysis. As broken DNA fragments in the tail migrate more quickly than larger pieces of DNA of the head, a blur of fragments (a "comet") is observed when the DNA is extensively damaged. The extent of DNA damage can be estimated from the intensity of the comet tail relative to the total intensity (head plus tail) that reflects the amount of DNA breakage (Collins, 2004; OECD TG 489, 2016). Variations in the procedure permit the preferential detection of double-strand breaks under neutral conditions (Fairbairn et al., 1995; Olive, 2009) or inclusion of digestion of lesion-specific DNA repair enzymes in the procedure allows the detection of various DNA base alterations, such as oxidative base damage. (Pu et al., 2015; Glei et al., 2016; Collins et al., 2017). Comet assay has also been modified to detect DNA methylation status (Townsend et al., 2017). Finally, the high-throughput "CometChip" technique, based on the traditional comet assay, simultaneously follows DNA damage load over time in different cell lines in response to various genotoxicants (Weingeist et al., 2013; Ge et al., 2014). This method quantifies kinetics, differential sensitivity, and repair capacity within different genetic backgrounds at the level of an individual cell. Although the comet assay has proven to be a sensitive indicator of DNA damage with broad applicability, it is prone to yield false positive/uninterpretable findings under conditions of physiological and/or mechanical stress. It has been used most commonly with human lymphocytes (Fairbairn et al., 1995; Singh, 2000; Collins, 2004) and other mammalian cells (Tice et al., 2000), but it can be adapted to diverse species, including plants, worms, mollusks, fish, and amphibians (Cotelle and Férard, 1999; Lee and Steinert, 2003; Jha, 2004). This adaptability makes it well suited to use in environmental genetic toxicology. The applicability of the comet assay and other DNA damage assays to rodent testes (Bentley et al., 1994; Speit et al., 2009) makes these methods helpful in interpreting risks to germ cells.

The occurrence of DNA repair can serve as an easily measured indicator of DNA damage. Repair assays have been developed in microorganisms, cultured mammalian cells, and intact mammals (Table 9-2). Greater toxicity of a chemical in DNA-repair-deficient strains than in their repair-proficient counterparts (e.g., *rec*$^+$ and *rec*$^-$ in *Bacillus subtilis*) can serve as an indicator of DNA damage in bacteria (Takigami et al., 2002). Bacterial repair assays find occasional application, but are used less commonly today than historically. The measurement of unscheduled DNA synthesis (UDS), which is a measure of excision repair, is a mammalian DNA repair assay indicating that DNA has been damaged (Madle et al., 1994). UDS has been used with cultured hepatocytes with endogenous cytochrome P450 enzyme activities as well as tissues of intact animals, including hepatocytes (Madle et al., 1994), and germinal tissue (Bentley et al., 1994; Sotomayor and Sega, 2000). The absence

of UDS, however, does not provide evidence that DNA has not been damaged because some classes of damage are not readily excised. Based upon their analysis, Kirkland and Speit (2008) questioned the value of in vivo rodent liver UDS assay as follow-up to the positive findings of in vitro genotoxicity assays. Their analyses were based on the relative performance of three in vivo assays (liver comet, transgenic mutation, and bone marrow micronucleus) in predicting rodent carcinogens.

Besides specific DNA repair processes, the induction of general responses to genotoxic stress has been used as an indicator of genetic damage. The induction of DNA repair networks, known as the "SOS response," allows bacteria to survive sudden increases in DNA damage as detected by phage induction, colorimetry, or green fluorescent protein (GFP) reporter induction after the activation of SOS gene promoters (Quillardet and Hofnung, 1993; Yasunaga et al., 2004; Friedman et al., 2005; Michel, 2005; Oda et al., 2009). Another fluorescence-based screen, the growth arrest and DNA damage gene GADD45a-GFP assay, also called "Green Screen," detects genotoxic stress in human lymphoblastoid TK6 cells (Hastwell et al., 2009; Hughes et al., 2012). The stress response is detected by the genetic GFP reporter construct following p53-dependent expression from GADD45a promoter of the truncated *GADD45a* gene/GFP construct. The induction of fluorescence by mutagens, clastogens, and aneugens exhibits sensitivity toward genotoxicants comparable with other in vitro mammalian cell assays as well as a very high specificity (93%) (Birrell et al., 2009). The assay can be conducted with S9 metabolic activation and lends itself to automated detection by flow cytometry (Jagger et al., 2009).

Gene Mutations in Prokaryotes

The most common means of detecting mutations in microorganisms is selecting for reversion in strains that have a specific nutritional requirement differing from wild type members of the species; such strains are called auxotrophs. For example, the widely used assay developed by Bruce Ames and his colleagues is based on measuring reversion in several histidine auxotrophs in *Salmonella enterica* serovar Typhimurium, commonly called *S. typhimurium* (Ames et al., 1975).

In the Ames assay one measures the frequency of histidine-independent bacteria that arise in a histidine-requiring strain in the presence or absence of the chemical being tested. Auxotrophic bacteria are treated with the chemical of interest by one of several procedures (e.g., the standard plate-incorporation assay) and plated on medium that is deficient in histidine (Ames et al., 1975; Maron and Ames, 1983; Mortelmans and Zeiger, 2000). The assay is conducted using genetically different strains so that reversion by base pair substitutions and frameshift mutations in several DNA sequence contexts can be detected and distinguished. Since *Salmonella* does not metabolize promutagens in the same way as mammalian tissues, the assay is generally performed in the presence and absence of a rat liver S9 metabolic activation system. The Ames assay is commonly referred to as the *Salmonella–Escherichia coli*/mammalian-microsome reverse mutation assay although the activation system used is S9 (microsomes + cytosol) (OECD TG 471, 1997). Based on the current version of the OECD Ames test guideline, at least five strains of bacteria should be used that include four strains of *S. typhimurium* that revert at GC base pairs (TA1535; TA1537 or TA97a or TA97; TA98; and TA100) and the fifth strain that reverts at AT base pair (either one of *E. coli* WP2 uvrA, or *E. coli* WP2 uvrA (pKM101), or *S. typhimurium* TA102).

The principal strains of the Ames test and their characteristics are summarized in Table 9-3. In addition to the histidine alleles that provide the target for measuring mutagenesis, the Ames tester strains contain other genes and plasmids that enhance the assay. Part I of the table gives genotypes, and Part II explains the rationale for including specific genetic characteristics in the strains. Part III summarizes the principal DNA target in each strain and the mechanisms of reversion. Taken together, the Ames strains detect a broad array of mutations, and they complement one another. For example, *E. coli* and *S. typhimurium* oxidative damage-sensitive strains TA102 and TA104, all detect the A:T-to-G:C base pair substitutions that are not detected by *hisG46* strains (Mortelmans and Zeiger, 2000). TA102 also detects chemicals that cause DNA cross-links because it has an intact excision repair system whereas the other common tester strains do not.

The most common version of the Ames assay is the plate-incorporation test (Ames et al., 1975; Maron and Ames, 1983; Mortelmans and Zeiger, 2000). In this procedure, the bacterial tester strain, the test compound (or solvent control), and the S9 metabolic activation system (or buffer for samples without S9) are added to 2 mL of molten agar containing biotin and a trace of histidine to allow a few cell divisions, mixed, and immediately poured onto the surface of a petri dish selective for histidine-independent revertants. For general testing it is recommended that at least three plates per concentration and five concentrations be used with and without S9, along with appropriate concurrent positive and negative controls (Mortelmans and Zeiger, 2000). Variations on the standard plate-incorporation assay confer advantages for some applications. These include a preincubation assay that facilitates the detection of unstable compounds and short-lived metabolites, a desiccator assay for testing volatile chemicals and gases, a microsuspension assay for working with small quantities of test materials, assays incorporating reductive metabolism rather than the conventional S9 system, and assays under hypoxic conditions (Mortelmans and Zeiger, 2000).

Although simplicity is a great merit of microbial assays, it can also be deceptive. Even assays that are simple in design and application can be performed incorrectly. For example, in the Ames assay one may see very small colonies in the petri dishes at highly toxic concentrations (Maron and Ames, 1983; Kirkland et al., 1990; Mortelmans and Zeiger, 2000). Counting such colonies as revertants would be an error because they may actually be non-revertant survivors that grew on the low concentration of histidine in the plates. Were there millions of survivors, the amount of histidine would have been insufficient to allow any of them (except real revertants) to form colonies. This artifact is easily avoided by checking that there is a faint lawn of bacterial growth in the plates; one can also confirm that colonies are revertants by streaking them on medium without histidine to be sure that they grow in its absence. Such pitfalls exist in all mutagenicity tests. Therefore, anyone performing mutagenicity tests must have detailed familiarity with the laboratory application and literature of the assay and be observant about the responsiveness of the assay in terms of laboratory historical negative and positive control values.

Although information from the Ames assay has become a standard in genetic toxicology testing, equivalent information can be obtained from other bacterial assays. Like the Ames assay, the WP2 tryptophan reversion assay in *E. coli* (Kirkland et al., 1990; Mortelmans and Riccio, 2000) incorporates genetic features that enhance assay sensitivity, can accommodate S9 metabolic activation, and performs well in many laboratories. Mutations are detected by selecting for reversion of a *trpE* allele from Trp^- to Trp^+. Its responsiveness to mutagens most closely resembles TA102 among the Ames strains (Mortelmans and Riccio, 2000).

Bacterial reversion assays are commonly used for testing purposes, but they also provide information on molecular mechanisms of mutagenesis. The broader understanding of mutational mechanisms that comes from refined genetic assays and molecular analysis of mutations can contribute to the interpretation of mutational hazards. The primary reversion mechanisms of the Ames strains,

Table 9-3

The Ames Assay: Tester Strains and Their Characteristics

I. STANDARD TESTER STRAINS OF *SALMONELLA TYPHIMURIUM AND ESCHERICHIA COLI*

STRAIN	TARGET ALLELE	CHROMOSOMAL GENOTYPE	PLASMIDS
TA1535	*hisG46*	*hisG46 rfa ΔuvrB*	None
TA100	*hisG46*	*hisG46 rfa ΔuvrB*	pKM101 (*mucAB* Ap^r)
TA1538	*hisD3052*	*hisD3052 rfa ΔuvrB*	None
TA98	*hisD3052*	*hisD3052 rfa ΔuvrB*	pKM101 (*mucAB* Ap^r)
TA1537	*hisC3076*	*hisC3076 rfa ΔuvrB*	None
TA97	*hisD6610*	*hisD6610 hisO1242 rf ΔuvrB*	pKM101 (*mucAB* Ap^r)
TA102	*hisG428*	*hisΔ (G)8476 rfa*	pKM101 (*mucAB* Ap^r); pAQ1 (*hisG428* Tc^r)
TA104	*hisG428*	*hisG428 rfa ΔuvrB*	pKM101 (*mucAB* Ap^r)
E. coli WP2 *uvrA*	*trpE*	*trpE uvrA*	None
E. coli WP2 *uvrA* (pKM101)	*trpE*	*trpE uvrA*	pKM101 (*mucAB* Ap^r)

II. GENETIC CHARACTERISTICS OF THE AMES TESTER STRAINS

CHARACTERISTIC	RATIONALE FOR INCLUSION IN THE TESTER STRAIN
Rfa	Alters the lipopolysaccharide wall, enhancing permeability to mutagens.
ΔuvrB	Deletes the excision repair system, increasing sensitivity to many mutagens; retention of excision in TA102 permits the detection of DNA cross-linking agents.
mucAB	Enhances sensitivity to some mutagens whose activity depends on the SOS system.
Ap^r	Permits selection for the presence of pKM101 by ampicillin resistance.
hisO1242	Affects regulation of histidine genes, enhancing revertibility of *hisD6610* in TA97.
His Δ (G)8476	Eliminates the chromosomal *hisG* gene, allowing detection of the reversion of *hisG428* on pAQ1 in TA102.
Tc^r	Permits selection for the presence of pAQ1 in TA102 by tetracycline resistance.

III. MECHANISMS OF REVERSION DETECTED BY THE AMES TESTER STRAINS

STRAIN	PRIMARY TARGET*	MUTATIONS DETECTED
TA1535, TA100	GGG/CCC	Base-pair substitutions, principally those beginning at G:C base pairs (G:C→A:T; G:C→T:A; G:C→C:G). These strains also detect A:T→C:G but not A:T→G:C.
TA1538, TA98	CGCGCGCG/GCGCGCGC	Frameshift mutations, especially −2 frameshifts (−GC or −CG), +1 frameshifts, other small deletions, and some complex mutations.
TA1537	GGGGG/CCCCC	Frameshift mutations, mainly −1 (−G or −C; less frequently −T), but also some +CG frameshifts.
TA97	GGGGGG/CCCCCC	Frameshift mutations, combining the specificity of TA1537 at the primary target and with some characteristics of TA98.
TA102, TA104	TAA/ATT terminating ochre mutation	Base-pair substitutions, principally those beginning at A:T base pairs (A:T→G:C; A:T→T:A; A:T→C:G), but also G:C→T:A and G:C→A:T.
E. coli WP2 *uvrA* strains	TAA/ATT terminating ochre mutation	Base-pair substitutions, principally those beginning at A:T base pairs.

**The sequences before and after the backslash represent the two complementary strands of DNA.*

summarized in Table 9-3, were initially determined by genetic and biochemical means (Maron and Ames, 1983). An ingenious method called allele-specific colony hybridization greatly facilitated the molecular analysis of revertants in the Ames assay (Koch et al., 1994), and many spontaneous and induced revertants have been cloned or amplified by the polymerase chain reaction (PCR) and sequenced (Levine et al., 1994; DeMarini, 2000).

Part III of Table 9-3 is by necessity a simplification with respect both to targets and mechanisms of reversion of the Ames strains. Some mutations that bring about reversion to histidine independence fall outside the primary target, and the full target has been found to be as much as 76 base pairs in *hisD3052* (DeMarini et al., 1998). Other revertants can arise by suppressor mutations in other genes. It has been shown that *hisG46*, *hisG428*, *hisC3076*,

hisD6610, and *hisD3052* all revert by multiple mechanisms and that the spectrum of classes of revertants may vary depending on the mutagen, experimental conditions, and other elements of the genotype (Cebula and Koch, 1990; Prival and Cebula, 1992; DeMarini et al., 1998; Mortelmans and Zeiger, 2000).

The development of *Salmonella* strains that are highly specific with respect to mechanisms of reversion has made the identification of particular base pair substitutions more straightforward. These strains (TA7001–TA7006) each revert from *his*$^-$ to *his*$^+$ by a single kind of mutation (e.g., G:C to T:A), and collectively they permit the specific detection of all six possible base pair substitutions (Gee et al., 1994; Mortelmans and Zeiger, 2000; Kamber et al., 2009). The assay, referred to as Ames II, is usually conducted using a fluctuation test in 24-well plates, rather than the plate-incorporation or preincubation method. The ability to discern mutagens and nonmutagens is comparable to the standard Ames assay with nearly 84% agreement between the two tests (Kamber et al., 2009).

Specific reversion assays are also available in *E. coli*. One system, based on reversion of *lacZ* mutations in various *E. coli* strains, measures all six possible base pair substitutions (Cupples and Miller, 1989; Josephy, 2000) and five frameshift +G, −G, −CG, +A, and −A mutations in several sequence contexts detected by growth on lactose medium (Cupples et al., 1990; Josephy, 2000; Hoffmann et al., 2003). The versatility of the *lacZ* assay has been expanded through the introduction of useful characteristics into the strains parallel to those incorporated into the Ames strains. Among the features added to the *lacZ* assay are DNA repair deficiencies, permeability alterations, plasmid-enhanced mutagenesis, and enzymes of mutagen metabolism (Josephy, 2000).

Bacterial forward mutation assays, such as selections for resistance to arabinose or to purine or pyrimidine analogs in *Salmonella* (Jurado et al., 1994; Vlasakova et al., 2005), are also used in research and testing, although less extensively than reversion assays. A versatile forward mutation assay that has contributed greatly to an understanding of mechanisms of mutagenesis is the *lacI* system in *E. coli* (Calos and Miller, 1981; Halliday and Glickman, 1991). Mutations in the *lacI* gene, which encodes the repressor of the lactose operon, are easily identified by phenotype, cloned or amplified by PCR, and sequenced. The *lacI* gene is widely used as a target for mutagenesis both in *E. coli* and in transgenic mice, and thousands of *lacI*$^-$ mutants have been sequenced.

Genetic Alterations in Nonmammalian Eukaryotes

Gene Mutations and Chromosome Aberrations Many early studies of mutagenesis used yeasts, mycelial fungi, plants, and insects as experimental organisms. Even though well-characterized genetic systems permit the analysis of a diverse array of genetic alterations in these organisms (Table 9-2), they have been largely supplanted in genetic toxicology by bacterial and mammalian systems. Exceptions are to be found where the assays in nonmammalian eukaryotes permit the study of genetic endpoints that are not readily analyzed in mammals or where the organism has special attributes that fit a particular application.

The fruit fly, Drosophila, has long occupied a prominent place in genetic research. In fact, the first unequivocal evidence of chemical mutagenesis was obtained in Scotland in 1941 when Charlotte Auerbach and J.M. Robson demonstrated that mustard gas is mutagenic in Drosophila. Drosophila continues to be used in modern mutation research (Potter et al., 2000), but its role in genetic toxicology is now more limited. The Drosophila assay of greatest historical importance is the sex-linked recessive lethal (SLRL) test. A strength of the SLRL test is that it permits the detection of recessive lethal mutations at 600 to 800 different loci on the X chromosome by screening for the presence or absence of wild type males in the offspring of specifically designed crosses (Mason et al., 1987; Vogel et al., 1999). The genetic alterations include gene mutations and small deletions. The spontaneous frequency of SLRL is about 0.2%, and a significant increase over this frequency in the lineages derived from treated males indicates mutagenesis. Although it requires screening large numbers of fruit fly vials, the SLRL test yields information about mutagenesis in germ cells, which is lacking in all microbial and cell culture systems. However, means of exposure, measurement of doses, metabolism, and gametogenesis in insects differ from those in mammalian toxicology, thereby introducing doubt about the relevance of Drosophila assays to human genetic risk. Drosophila assays are also available for studying the induction of chromosome abnormalities in germ cells, specifically heritable translocations and sex-chromosome loss (Zimmering, 1982; Mason et al., 1987; Vogel et al., 1999).

Genetic and cytogenetic assays in plants (Ma et al., 2005; Grant and Owens, 2006; Misík et al., 2011) also occupy a more restricted niche in modern genetic toxicology than they did years ago. However, plant assays continue to find use in special applications, such as in situ monitoring for mutagens and exploration of the metabolism of promutagens by agricultural plants (Gentile et al., 1986). In situ monitoring entails looking for evidence of mutagenesis in organisms that are grown in the environment of interest. Natural plant populations can also be examined for evidence of genetic damage, but doing so requires utmost precaution when characterizing the environments and defining appropriate control populations.

Mitotic Recombination In addition to its role in DNA repair, recombination (or the rearrangement between two similar or identical DNA sequences) provides critical support for the tolerance of DNA damage (Li and Heyer, 2008). The *RAD52* epistasis group genes are involved in homologous DNA recombination, and their primary structures are conserved from yeast to humans (Sonoda et al., 2001). Recombinogenic effects in yeast have long been used as a general indicator of genetic damage (Zimmermann et al., 1984), and interest in the induction of recombination has increased as recombinational events between chromosomes have been implicated in the etiology of cancer, including loss of heterozygosity (LOH) of one normal allele of tumor-suppressor genes such as *p53* (Sengstag, 1994; Reliene et al., 2007). Widely used assays for recombinogens detect mitotic crossing over and mitotic gene conversion in the yeast *Saccharomyces cerevisiae* (Zimmermann, 1992), and hundreds of chemicals have been tested for recombinogenic effects in straightforward yeast assays (Zimmermann et al., 1984). In yeast strain D7, for example, mitotic crossing over involving the *ade2* locus is detected on the basis of pink and red colony color, mitotic gene conversion at the *trp5* locus by selection for growth without tryptophan, and gene mutations by reversion of the *ilv1-92* allele (Zimmermann, 1992; Freeman and Hoffmann, 2007). Newer yeast assays have been constructed to discern whether LOH has occurred by mitotic recombination or chromosome loss (Daigaku et al., 2004; Nunoshiba et al., 2007). Strategies have also been devised to detect recombinogenic effects in human lymphocytes (Turner et al., 2003), other mammalian cells, mice, chickens, plants, and mycelial fungi (Hoffmann, 1994; Sonoda et al., 2001; Reliene et al., 2007). At least 350 chemicals have been evaluated in Drosophila somatic cell assays in which recombinogenic effects are detected by examining wings or eyes for regions in which recessive alleles are expressed in heterozygotes (Vogel et al., 1999; Vogel and Nivard, 2000).

Gene Mutations in Mammalian Cells

Mutagenicity assays in cultured mammalian cells have some of the same advantages as microbial assays with respect to speed and cost, and they use similar approaches. The most widely used assays for gene mutations in mammalian cells detect forward mutations that confer resistance to a toxic chemical. For example, mutations in the gene encoding hypoxanthine-guanine phosphoribosyltransferase (HPRT enzyme; *HPRT* gene) confer resistance to the purine analogue 6-thioguanine (Li et al., 1988; Parry et al., 2005), and thymidine kinase mutations (TK enzyme; *tk* gene) confer resistance to the pyrimidine analogue trifluorothymidine (Clive et al., 1987; Clements, 2000; Wang et al., 2009; Schisler et al., 2013). *HPRT* and *tk* mutations may, therefore, be detected by attempting to grow cells in the presence of purine analogues and pyrimidine analogues, respectively. For historical reasons, HPRT assays have most commonly been conducted in Chinese hamster cells or human cells, whereas TK assays have used mouse lymphoma cells or human cells. The mouse lymphoma assay, long used for detecting gene mutations, is now also used to detect other endpoints, including recombination, deletion, and aneuploidy (Wang et al., 2009). Forward-mutation assays typically respond to diverse mechanisms of mutagenesis, but there are exceptions such as resistance to ouabain, which only occurs by a specific alteration (DeMarini et al., 1989). Assays that do not detect various kinds of mutations are not useful for general mutagenicity testing. Genetic or molecular evidence that an assay is responsive to diverse mechanisms of mutagenesis is essential.

Instead of using selective media, flow cytometry can be used to detect gene mutations by immunological methods in mammalian cell cultures and intact animals. An in vitro assay for CD59 mutations is performed in CHO-human hybrid A_L cells based on the complement/antibody-mediated cytotoxicity principle (Zhou et al., 2006). A_L cells contain a single human chromosome 11 that expresses CD59 and other cell surface proteins along with the Chinese hamster chromosome complement of the Chinese hamster ovary (CHO) cells. Fluorescent anti-CD59 antibody is used to quantify CD59 mutant cells by flow cytometry. Besides CD59 itself, mutations in other CD genes on chromosome 11 and in their glycosylphosphatidylinositol anchor can be detected in other assays, including the in vivo *Pig-a* gene mutation assay described below (Ross et al., 2007; Krüger et al., 2016; Rees et al., 2017).

Gene Mutations In Vivo

In vivo assays involve treating intact animals and analyzing appropriate tissues for genetic effects. The choice of suitable doses, treatment procedures, controls, and sample sizes is critical in the conduct of in vivo tests. Mutations may be detected either in somatic cells or in germ cells. The latter are of special interest with respect to risk for future generations.

The mouse spot test is a traditional genetic assay for gene mutations in somatic cells (Styles and Penman, 1985; Lambert et al., 2005). Visible spots of altered phenotype in mice heterozygous for coat-colored genes indicate mutations in the progenitor cells of the altered regions. Although straightforward in design, the spot test is less used today than other somatic cell assays or than its germ cell counterpart, the mouse specific-locus test.

Cells that are amenable to positive selection for mutants when collected from intact animals form the basis for efficient in vivo mutation-detection assays analogous to those in mammalian cell cultures. Lymphocytes with mutations in the *HPRT* gene are readily detected by selection for resistance to 6-thioguanine. The HPRT assay in mice, rats, and monkeys (Casciano et al., 1999) is of special interest because it permits comparisons to the measurement of *HPRT* mutations in humans in mutational monitoring (Cole and Skopek, 1994; Albertini and Hayes, 1997; Albertini, 2001).

The *Pig-a* mutation assay is a newer assay that has versions suitable for human monitoring and laboratory studies in several species (Gollapudi et al., 2015; Ji and LeBaron, 2017). The assay detects mutations that block the transmembrane anchor glycosylphosphatidylinositol (GPI) synthesis (Dobrovolsky et al., 2010). *Pig-a* is a sex-linked, single copy gene whose gene product, the catalytic subunit of an *N*-acetyl glucosamine transferase, functions as an anchor for cell-surface proteins such as CD59, CD24, and CD55 to the exterior surface of the cytoplasmic membrane. The *Pig-a* mutation assay is based on the identification of mutant cells that have an altered repertoire of cell surface markers. Mutations in *Pig-a* can be detected in red blood cells from rats, mice, monkeys, and humans by means of fluorescent antibodies against GPI-anchored cell-surface proteins, such as CD59. The *Pig-a* mutation assay was also applied to rat cauda epididymal spermatozoa (sperm) for germ cell mutagenicity evaluation (Ji and LeBaron, 2017). Using antibodies to more than one GPI-linked marker has been suggested as a means of making the assay specific to *Pig-a* rather than also detecting mutants for a particular cell-surface protein. Frequencies can be measured by clonal growth of *Pig-a* cells using proaerolysin (ProAER) selection or by flow cytometry (Dobrovolsky et al., 2010; Dobo et al., 2011; Miura et al., 2011; Ji and LeBaron, 2017). Since this assay is performed using red blood cell, one of the challenges has been to confirm the mutant phenotype is indeed due to alteration at the DNA level (genotype) since red blood cells in mammals do not have nuceli to sequence DNA. Attempts are currently underway to collect this information by attempting to sequence the gene transcript in reticulocytes and by studying the nucleated bone marrow progenitor cells.

Besides determining whether chemicals are mutagenic, mutation assays provide information on mechanisms of mutagenesis that contributes to an understanding of mutational hazards. Base pair substitutions and large deletions, which may be indistinguishable on the basis of phenotype, can be differentiated through the use of probes for the target gene and Southern blotting, in that base substitutions are too subtle to be detectable on the blots, whereas gross structural alterations are visible (Cole and Skopek, 1994; Albertini and Hayes, 1997). Molecular analysis has been used to determine proportions of mutations ascribable to deletions and other structural alterations in several assays, including the specific-locus test for germ cell mutations in mice (Favor, 1999) and the human HPRT assay (Cole and Skopek, 1994). Gene mutations have been characterized at the molecular level by DNA sequence analysis both in transgenic rodents (Lambert et al., 2005; Singer et al., 2006) and in endogenous mammalian genes (Cariello and Skopek, 1993). Many *HPRT* mutations from human cells in vitro and in vivo have been analyzed at the molecular level and classified with respect to base pair substitutions, frameshifts, small deletions, large deletions, and other alterations (Cole and Skopek, 1994).

Transgenic Assays Transgenic animals are products of DNA technology in which the animal contains foreign DNA sequences that have been added to the genome. The foreign DNA is represented in all the somatic cells of the animal and is transmitted in the germ line to progeny. Mutagenicity assays in transgenic animals combine in vivo metabolic activation and pharmacodynamics with simple microbial detection systems, and they permit the analysis of mutations induced in diverse mammalian tissues (Lambert et al., 2005; Sykes et al., 2006; Valentine et al., 2010; OECD TG 488, 2013).

The transgenic animals that have figured most heavily in genetic toxicology are rodents that carry *lac* genes from *E. coli*. The bacterial genes were introduced into mice or rats by injecting a vector carrying the genes into fertilized oocytes generating grown up transgenic animals containing multiple copies of chromosomally integrated plasmid or phage shuttle vectors. (Lambert et al., 2005; OECD TG 488, 2013). The Mammalian Transgenic Rodent (TGR) mutation assays are performed with strains commonly referred to by their commercial names: the Big Blue® mouse and Big Blue® rat, which use *lacI* as a target for mutagenesis, and the Muta™ Mouse, which uses the *lacZ* target gene (Lambert et al., 2005; OECD TG 488, 2013). After mutagenic treatment of the transgenic animals, the *lac* genes are recovered from the animal, packaged in phage λ, and transferred to *E. coli* for mutational analysis. Mutant plaques are identified on the basis of phenotype, and mutant frequencies can be calculated for various tissues of the treated animals. The lambda *cII* locus of the transgene may be used as a second target gene in both the *lacZ* and *lacI* transgenic assays (Swiger et al., 1999; Shane et al., 2000; Swiger, 2001; Lambert et al., 2005). Its use offers technical advantages as a small, easily sequenced target in which mutations are detected by positive selection, and it permits interesting comparisons both within and between assays.

The transgenic *lacZ* plasmid mouse uses a plasmid-based system rather than a phage vector and has the advantage that deletion mutants are more readily recovered than in the phage-based *lac* systems (Lambert et al., 2005; OECD TG 488, 2013). The *gpt delta* mouse and rat transgenic animals detect two kinds of genetic events in two targets: point mutations in *gpt* detected by resistance to 6-thioguanine and *spi* (or Sensitive to P2 Interference) deletions that permit growth on P2 lysogens (Okada et al., 1999; Lambert et al., 2005; Cao et al., 2014; OECD TG 488, 2013). The *Spi*⁻ assay uniquely allows analyses of deletions and complex DNA rearrangements induced by DNA double-strand breaks using a phage vector system (Nohmi, 2016; OECD TG 488, 2013). Other transgenic assays are under development and offer the prospect of expanding the versatility of such assays (Lambert et al., 2005). These include pKZ1 mice in which inversions and deletions arising in various tissues by intrachromosomal recombination have been used to study effects of low doses of ionizing radiation (Sykes et al., 2006) and an assay that detects both forward mutations and reversion in mice that carry the genome of phage ΦX174 (Valentine et al., 2010).

Various mutagens, including alkylating chemicals, nitrosamines, procarbazine, cyclophosphamide, and polycyclic aromatic hydrocarbons have been studied in transgenic mouse assays, and mutant frequencies have been analyzed in such diverse tissues as liver, skin, spleen, kidney, bladder, small intestine, bone marrow, and testis (Lambert et al., 2005). Mutation frequencies in transgenes in testes have been compared to results in standard germ cell mutagenesis assays (Singer et al., 2006). Female germ cells are less amenable to study in transgenic assays because of the difficulty of collecting sufficient numbers of oocytes, but it has been suggested that granulosa cells from ovarian follicles may serve as a surrogate for the exposure of female germ cells to mutagens (Singer et al., 2006). Mutant frequencies have been compared to the formation of adducts in various tissues and to the site specificity of carcinogenesis and DNA repair capacity (Lambert et al., 2005). An important issue that remains to be resolved is the extent to which transgenes resemble endogenous genes. Transgenes used in routine mutation assays are transcriptionally inactive and hence differ from transcriptionally endogenous genes in their accessibility to mutagenesis as well as capability for repair. Although their mutational responses tend to be comparable (Lambert et al., 2005), some differences have been noted (Burkhart and Malling, 1993; Lambert et al., 2005), and questions have been raised about the relevance of mutations that might be recovered from dying or dead animal tissues (Burkhart and Malling, 1994). Several of the transgenic mutation assays have been adequately characterized to the point that there is an OECD test guideline for the conduct of these assays in somatic and germ cells (OECD TG 488, 2013).

Mammalian Cytogenetic Assays

Chromosome Aberrations Cytogenetic assays rely on the use of microscopy for the direct observation of the effects of interest. This approach differs sharply from the indirectness of traditional genetic assays in which one observes a phenotype and reaches conclusions about genes. It is only through the addition of DNA sequencing that genetic assays can approach the directness of cytogenetic assays.

In conventional cytogenetics, metaphase analysis is used to detect chromosomal anomalies, especially unstable chromosome and chromatid aberrations. A key factor in the design of cytogenetic assays is obtaining appropriate cell populations for treatment and analysis (Preston et al., 1981; Ishidate et al., 1988; Kirkland et al., 1990; Galloway et al., 1994). Cells with a stable, well-defined karyotype, short generation time, low chromosome number, and large chromosomes are ideal for cytogenetic analysis. For this reason, Chinese hamster cells have been used widely in cytogenetic testing. Other cells are also suitable, and human cells, especially peripheral lymphocytes, have been used extensively. Cells should be treated during a sensitive period of the cell cycle (typically S), and aberrations should be analyzed at the first mitotic division after treatment so that the sensitivity of the assay is not reduced by unstable aberrations being lost during cell division. Examples of chromosome aberrations are shown in Fig. 9-6.

Cytogenetic assays require careful attention to growth conditions, controls, dose levels, treatment conditions, and time intervals between treatment and the sampling of cells for analysis

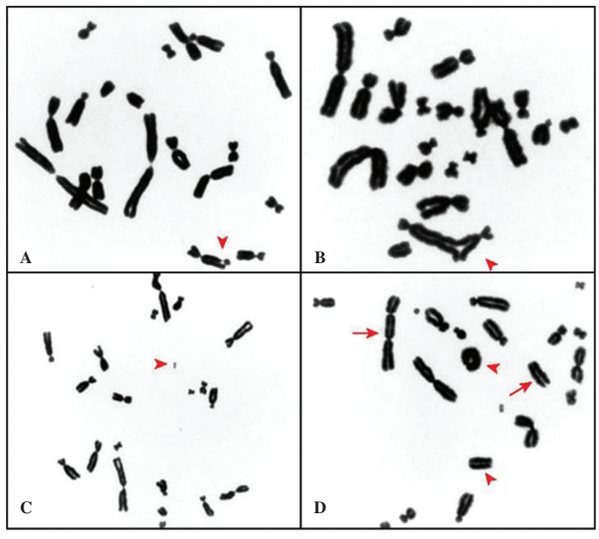

Figure 9-6. *Chromosome aberrations induced by x-rays in Chinese hamster ovary (CHO) cells.* (**A**) A chromatid deletion (▸). (**B**) A chromatid exchange called a triradial (▸). (**C**) A small interstitial deletion (▸) that resulted from chromosome breakage. (**D**) A metaphase with more than one aberration: a centric ring plus an acentric fragment (▸) and a dicentric chromosome plus an acentric fragment (→).

(Preston et al., 1981; Ishidate et al., 1988; Kirkland et al., 1990; Galloway et al., 2011). Data collection is a critical part of cytogenetic analysis. It is essential that sufficient cells be analyzed because a negative result in a small sample is inconclusive. Results should be recorded for specific classes of aberrations, not just an overall index of aberrations per cell. The need for detailed data is all the more important because of nonuniformity in the classification of aberrations and disagreement on whether small achromatic (i.e., unstained) gaps in chromosomes are true chromosomal aberrations. Gaps should be quantified but not pooled with other aberrations.

In interpreting results on the induction of chromosome aberrations in cell cultures, one must be alert to the possibility of artifacts associated with extreme assay conditions because aberrations induced under such circumstances may not be a reflection of a chemical-specific genotoxicity (Scott et al., 1991; Galloway, 2000; Galloway et al., 2011). Questionable positive results have been found at highly cytotoxic concentrations (Galloway et al., 2011), high osmolality, and pH extremes (Scott et al., 1991). The possibility that metabolic activation systems may be genotoxic also warrants scrutiny (Scott et al., 1991). Although excessively high concentrations may lead to false positive responses, the failure to test to a sufficiently high dose level may undermine the utility of a test. Therefore, testing should be extended to a concentration at which there is some cytotoxicity, such as a reduction in a replicative index or the mitotic index (the proportion of cells in division cycle). If the chemical is nontoxic, testing concentrations should extend up to an arbitrary concentration limit (Galloway et al., 2011). By a consensus of cytogeneticists and genetic toxicologists, the limit of 10 mM or 2 mg/mL, whichever is lower, has been recommended (Thybaud et al., 2017). However, the limit dose for the evaluation of human pharmaceuticals has been agreed to 1 mM (Galloway, 2017).

In vivo assays for chromosome aberrations involve treating intact animals and later collecting cells for cytogenetic analysis (Preston et al., 1981; Kirkland et al., 1990; Tice et al., 1994). The main advantage of in vivo assays is that they include mammalian metabolism, DNA repair, and pharmacodynamics. The target is typically a tissue from which large numbers of dividing cells are easily prepared for analysis. Bone marrow from rats, mice, or Chinese hamsters is most commonly used. Peripheral lymphocytes are another suitable target when stimulated to divide with a mitogen such as phytohemagglutinin. Effective testing requires dosages and routes of administration that ensure adequate exposure of the target cells, proper intervals between treatment and collecting cells, and sufficient numbers of animals and cells analyzed (Preston et al., 1981; Kirkland et al., 1990; Tice et al., 1994).

An important development in cytogenetic analysis is fluorescent in situ hybridization (FISH), in which a nucleic acid probe is hybridized to complementary sequences in chromosomal DNA (Tucker et al., 1993b, 2005; Paccierotti and Sgura, 2008). The probe is labeled with a fluorescent dye so that the chromosomal location to which it binds is visible by fluorescence microscopy, and the signal can be increased in strength by computer-enhanced processes. The use of whole-chromosome probes probed during metaphase or interphase nuclei is commonly called "chromosome painting" (Tucker et al., 1993b; Speicher and Carter, 2005; Paccierotti and Sgura, 2008). The level of sophistication has increased so much that all 24 different human chromosomes (22 autosomes, X and Y) can be individually detected (Macville et al., 1997), as can all mouse chromosomes (Liyanage et al., 1996).

Although FISH is not routinely used in genotoxicity testing, it is a valuable research tool for studying clastogens and is having a substantial impact in monitoring human populations for chromosomal damage. Fig. 9-7 shows chromosome painting and reciprocal translocations in human cancer cell. Regions of hybridization can be determined by the use of fluorescent antibodies that detect modified DNA bases incorporated during amplification or by incorporating fluorescent bases themselves during amplification. Another significant advantage of FISH methods is that the probes can be used with interphase cells/chromosomes making any tissue potentially available for analysis (Trask et al., 1993; Speicher and Carter, 2005; Vorsanova et al., 2010). Most recently, M-FISH (multicolor FISH) and M-BAND (multicolor banding) have been developed for defining chromosome abnormalities (Mackinnon and Chudoba, 2011). Alterations in tumors can also be detected on a whole-genome basis (Coleman et al., 1997; Veldman et al., 1997; Bridge and Cushman-Vokoun, 2011). The following example highlights the ability to construct breakpoint profiles of specific tumor types (Trost et al., 2006). One of the best known examples of a chromosomal breakpoint is the Philadelphia chromosome, a translocation abnormality of chromosome 22 containing a part of chromosome 9 that is often found in chronic myelogenous leukemia and sometimes in acute lymphocytic leukemia. In translocations, the involvement of specific chromosome bands that contain oncogenes or tumor-suppressor genes is also known.

Specifically, in chromosome 4 painted with a probe while the other chromosomes were counter-stained in a different color, one would see only the two homologues of chromosome 4 in the color of the probe in a normal cell. However, if there were a translocation or a dicentric chromosome and fragment involving chromosome 4, one would see three areas of fluorescence—one normal chromosome 4 and the two pieces involved in the chromosome rearrangement. Aberrations are detected only in the painted portion of the genome, but this disadvantage can be offset by painting a few chromosomes simultaneously with probes of different colors (Tucker et al., 1993b).

Micronuclei Metaphase analysis is time consuming and requires considerable skill, so simpler cytogenetic assays have been developed, of which micronucleus assays have become especially important. Micronuclei are membrane-bound structures that contain chromosomal fragments, or sometimes whole chromosomes,

Figure 9-7. *Chromosome aberrations identified by FISH.* Human breast cancer cell with aneuploidy for some chromosomes and with reciprocal translocations (identified by color switches along a chromosome).

that were not incorporated into a daughter nucleus at mitosis. Since micronuclei usually represent acentric chromosomal fragments, these are most commonly used as simple indicators of chromosomal damage. However, the ability to detect micronuclei containing whole chromosomes has led to their use for detecting aneuploidy as well. Micronucleus assays may be conducted in primary cultures of human lymphocytes (Fenech et al., 2003; Corvi et al., 2008; Fenech, 2008; Fenech et al., 2011b), mammalian cell lines (Kirsch-Volders et al., 2003; Corvi et al., 2008), or mammals in vivo (Krishna and Hayashi, 2000; Hayashi et al., 2007; Dertinger et al., 2011).

Micronucleus assays in lymphocytes have been greatly improved by the cytokinesis-block technique in which cell division is inhibited with cytochalasin B, resulting in binucleate and multinucleate cells (Fenech et al., 2003, 2011b; Kirsch-Volders et al., 2003; Fenech, 2008). In the cytokinesis-block assay in human lymphocytes, non-dividing (G_0) cells are treated with ionizing radiation or a radiomimetic chemical and then stimulated to divide with the mitogen phytohemagglutinin. Alternatively, the lymphocytes may be exposed to the mitogen first, so that the subsequent mutagenic treatment with radiation or chemicals includes the S period of the cell cycle. Cytochalasin B is added to inhibit the actin filament network formation and cytoplasmic division along with the test material when treating the cells continuously for 1.5 to 2 cell cycles in the absence of S9. For short duration exposures (e.g., 2-4 h), cytochalasin B is added at the end of treatment and the cultures are harvested also after 1.5 to 2 cell cycles. In both cases, micronuclei are counted only in binucleate cells so as to ensure that the cells have undergone a single nuclear division that is essential for micronucleus development. The assay avoids confusion owing to differences in cellular proliferation kinetics.

Although first devised using primary lymphocytes (Fenech et al., 2003; Fenech, 2008; Fenech et al., 2011b), the cytokinesis-block micronucleus assay has since been adapted for use in continuous cell cultures, including the Chinese hamster, human TK6, and mouse lymphoma cells that are widely used in other genotoxicity assays (Kirsch-Volders et al., 2003; Corvi et al., 2008). Micronucleus assays should be conducted in such a way that cellular proliferation is monitored along with the micronucleus frequency, and this is facilitated by the cytokinesis block. Reliable data have been obtained in cultured cells both with and without cytokinesis block, but scoring results only in binucleate cells after blockage of cytokinesis with cytochalasin B confers advantages with respect to the measurement of proliferation, recognizing whether an agent is cytostatic, and obtaining clear dose–response relationships (Kirsch-Volders et al., 2003).

Although micronuclei resulting from chromosome breakage comprise the principal endpoint in the cytokinesis-block micronucleus assay, the method can also provide evidence of aneuploidy, chromosome rearrangements that form nucleoplasmic bridges, inhibition of cell division, necrosis, apoptosis, and excision-repairable lesions (Fenech et al., 2003; Fenech, 2008; Fenech et al., 2011b). Micronuclei in a binucleate human lymphocyte are shown in Fig. 9-8. A recent review of the International Human Micronucleus (HUMN) Project provides a comprehensive description of standardized protocols for micronucleus assays in human lymphocytes and buccal cells together with a review of associations between micronucleus data and disease outcomes (Fenech et al., 2011a).

The in vivo micronucleus assay is often performed by counting micronuclei in immature (polychromatic) erythrocytes in the bone marrow of treated mice, but it may also be based on peripheral blood (Krishna and Hayashi, 2000; Hayashi et al., 2007). Micronuclei remain in the cell when the nucleus is extruded in the maturation of erythroblasts. In vivo micronucleus assays are increasingly used in genotoxicity testing as a substitute for bone marrow metaphase chromosome analysis. Micronucleus assays have been developed for mammalian tissues other than bone marrow and blood, including skin, duodenum, colon, liver, lung, spleen, testes, bladder, buccal mucosal cells, stomach, vagina, and fetal tissues (Coffing et al., 2011; Morita et al., 2011). Although assays in bone marrow and blood are the mainstay of genotoxicity testing, the new assays are important for mechanistic studies and research on the site specificity of genetic damage and carcinogenesis.

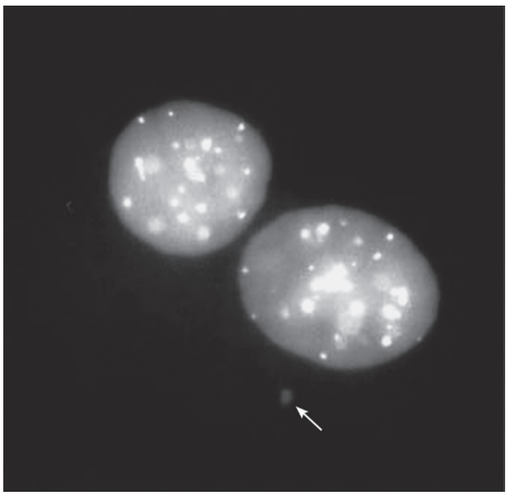

Figure 9-8. *Micronucleus in a human lymphocyte.* The cytochalasin B method was used to inhibit cytokinesis that resulted in a binucleate nucleus. The micronucleus (arrow) resulted from failure of an acentric chromosome fragment or a whole chromosome being included in a daughter nucleus following cell division. (Figure courtesy of James Allen, Jill Barnes, and Barbara Collins.)

Micronuclei are most commonly visualized through microscopy, but automated means of detecting micronuclei have been developed through the application of flow cytometry. Flow cytometric detection is effective in micronucleus assays in rodent bone marrow or blood (Dertinger et al., 2011). It can also be used to detect micronuclei in Chinese hamster CHO cells, where altered flow cytometric parameters can reveal whether the micronuclei arose primarily by chromosome breakage or by aneuploidy (Bryce et al., 2011).

Sister Chromatid Exchanges (SCE) Sister Chromatid Exchanges (SCE), in which there has been an apparently reciprocal exchange of segments between the two chromatids of a chromosome, are visible cytologically through differential staining of chromatids. Fig. 9-9 shows SCE in human cells. Many mutagens induce SCE in cultured cells and in mammals in vivo (Tucker et al., 1993a; Wilson and Thompson, 2007). Despite the convenience and responsiveness of SCE assays, data on SCE are less informative than data on chromosome aberrations. There is uncertainty about the underlying mechanisms by which SCEs are formed and how DNA damage or perturbations of DNA synthesis stimulate their formation (Preston, 1991). SCE assays are, therefore, best regarded as general indicators of mutagen exposure, analogous to DNA damage and repair assays, rather than measures of a mutagenic effect.

Aneuploidy Although assays for the induction of aneuploidy are not yet as refined as those for gene mutations and chromosome aberrations, they are being developed. The targets of aneugens

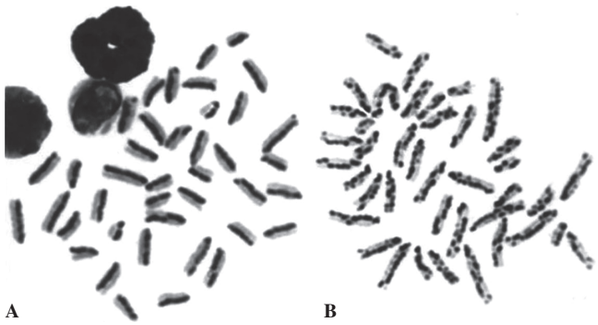

Figure 9-9. *Sister chromatid exchanges (SCEs) in human lymphocytes.* (**A**) SCE in untreated cell. (**B**) SCE in cell exposed to ethyl carbamate. The treatment results in a very large increase in the number of SCE. (Figure courtesy of James Allen and Barbara Collins.)

are often components of the mitotic or meiotic apparatus, rather than DNA. Therefore, aneugens should not be expected to overlap strongly with mutagens and clastogens. For example, a chemical that interferes with the polymerization of tubulin and thereby disrupts the formation of a mitotic spindle is likely to show specificity as an aneugen. Assays for chemicals that induce aneuploidy should thus encompass all the relevant cellular targets that are required for the proper functioning of the mitotic and meiotic process. Means of detecting aneuploidy include chromosome counting (Galloway and Ivett, 1986; Natarajan, 1993; Aardema et al., 1998; Paccierotti and Sgura, 2008), the detection of micronuclei that contain kinetochores (Lynch and Parry, 1993; Natarajan, 1993; Aardema et al., 1998; Fenech, 2008; Paccierotti and Sgura, 2008), and the observation of abnormal spindles or spindle–chromosome associations in cells in which spindles and chromosomes have been differentially stained (Parry, 1998). FISH-based assays have also been developed for the assessment of aneuploidy in interphase somatic cells (Rupa et al., 1997; Paccierotti and Sgura, 2008) and in sperm (Russo, 2000; Marchetti et al., 2006, 2008).

A complication in chromosome counting is that a metaphase may lack chromosomes because they were lost during cell preparation for analysis, rather than having been absent from the living cell. To avoid this artifact, cytogeneticists generally use extra chromosomes (i.e., hyperploidy) rather than missing chromosomes (i.e., hypoploidy) as an indicator of aneuploidy in chromosome preparations from mammalian cell cultures (Galloway and Ivett, 1986; Aardema et al., 1998) or mouse bone marrow (Adler, 1993). Techniques for counting chromosomes in intact cells may allow reliable measures of hypoploidy (Natarajan, 1993), but the detection of hyperploidy remains the norm in lieu of clear evidence that artifactual chromosome loss has been avoided. It has been suggested that counting polyploid cells, which is technically straightforward, may be an efficient way to detect aneugens (Aardema et al., 1998), but there is disagreement on the point (Parry, 1994, 1998).

Micronucleus assays can detect aneugens as well as clastogens. Micronuclei that contain whole chromosomes tend to be somewhat larger than those containing chromosome fragments, but the two categories are not readily distinguished in typically stained preparations (Natarajan, 1993). However, one can infer that a micronucleus contains a whole chromosome if it is shown to contain a kinetochore or centromeric DNA. Aneuploidy may thus be detected by means of antikinetochore antibodies with a fluorescent label or FISH with a probe for centromere-specific DNA (Lynch and Parry, 1993; Natarajan, 1993; Krishna and Hayashi, 2000; Fenech, 2008; Paccierotti and Sgura, 2008). Micronuclei containing kinetochores or centromeric DNA may be detected in cultured cells (Lynch and Parry, 1993; Aardema et al., 1998; Fenech, 2008; Paccierotti and Sgura, 2008) and in mouse bone marrow in vivo (Adler, 1993; Krishna and Hayashi, 2000). Frequencies of micronuclei ascribable to aneuploidy and to clastogenic effects may therefore be determined concurrently by tabulating micronuclei with and without kinetochores.

Germ Cell Mutagenesis

Gene Mutations Germ cell mutagenesis assays are of special interest as indicators of genetic damage that can enter the gene pool and be transmitted through generations. Mammalian germ cell assays provide the best basis for assessing risks to human germ cells and therefore hold a central place in genetic toxicology despite their relative complexity and expense. The design of the test must compensate for the fact that mutations occur at low frequency, and even the simplest animal systems face the difficulty of having a sufficiently large sample size. One can easily screen millions of bacteria or cultured cells by selection techniques, but screening large numbers of mice poses practical limitations. Therefore, a germ cell assay must offer a straightforward, unequivocal identification of mutants with minimal labor (Singer and Yauk, 2010; Yauk et al., 2015).

The mouse specific-locus test detects recessive mutations that produce easily analyzed, visible phenotypes (coat pigmentation and ear size) conferred by seven genes (Russell and Shelby, 1985; Ehling, 1991; Russell and Russell, 1992; Favor, 1999; Russell, 2004; Singer et al., 2006). Mutants may be classified as having point mutations or chromosomal alterations on the basis of genetic and molecular analysis (Favor, 1999). The assay has been important in assessing genetic risks of ionizing radiation and has been used to study various chemical mutagens. Although they have been used less extensively, there are other gene-mutation assays in mouse germ cells based on dominant mutations that cause skeletal abnormalities (Selby et al., 2004) or cataracts (Ehling, 1991) and recessive mutations that cause electrophoretic changes in proteins (Lewis, 1991).

Mammalian assays permit the measurement of mutagenesis at different germ cell stages (Favor, 1999; Russell, 2004). Late stages of spermatogenesis are often found to be sensitive to mutagenesis, but effects in spermatocytes, spermatids, and spermatozoa are transitory. Mutagenesis in stem-cell spermatogonia and resting oocytes is of special interest in genetic risk assessment because of the persistence of these stages throughout reproductive life. Chemical mutagens show specificity with respect to germ cell stages. For example, ethylnitrosourea and chlorambucil are both potent mutagens in the mouse specific-locus test, but the former induces primarily point mutations in spermatogonia, whereas the latter mostly induces deletions in spermatids (Russell and Russell, 1992). The ratio of deletions to point mutations is not only a function of the nature of the mutagen but depends on germ cell stage, as some mutagens induce higher proportions of gross alterations in late stages of spermatogenesis than in spermatogonia (Lewis, 1991; Favor, 1999; Russell, 2004).

There is currently no unequivocal evidence of induced gene mutations in human germ cells, but studies in mice leave little doubt about the susceptibility of mammalian germ cells to mutagenesis by radiation and chemicals. New molecular methods, particularly those involving the assessment of changes in tandem repeat loci (Yauk, 2004; Dubrova, 2005; Singer et al., 2006; Somers, 2006; Yauk et al., 2015), hold great promise for the development of systems that will permit the efficient detection of genetic alterations in human germ

cells. The development of methods based on expanded simple tandem repeat (ESTR) loci in mice and other species is important, in that it permits in situ monitoring for environmental mutagens and the quantification of mutagenesis after controlled exposures of laboratory animals using systems parallel to those being developed for human monitoring (Yauk, 2004; Dubrova, 2005; Wu et al., 2006; Somers, 2006). Basic research on mechanisms underlying ESTR changes is essential, as it is still unclear how ESTR changes relate to the gene mutations that have been long studied by population geneticists and are detected in classical gene-mutation assays.

Chromosomal Alterations Cytogenetic assays in germ cells are not routinely included in mutagenicity testing, but they are an important source of information for assessing risks to future generations posed by the induction of chromosome aberrations. Metaphase analysis of germ cells is feasible in rodent spermatogonia, spermatocytes, or oocytes (Kirkland et al., 1990; Tease, 1992; Russo, 2000; Marchetti et al., 2001). A micronucleus assay has also been developed in which chromosomal damage induced in meiosis is measured by the observation of rodent germ cells, principally spermatids (Russo, 2000; Hayashi et al., 2007).

Aneuploidy originating in mammalian germ cells may be detected cytologically through chromosome counting for hyperploidy (Allen et al., 1986; Adler, 1993; Aardema et al., 1998; Russo, 2000; Marchetti et al., 2001) or genetically in the mouse sex-chromosome loss test (Russell and Shelby, 1985), but these methods are not widely used in toxicological testing. A promising development is the detection of aneuploidy in the sperm of mice or rats by FISH with chromosome-specific probes (Baumgarthner et al., 1999; Russo, 2000; Marchetti et al., 2006, 2008). The presence of two fluorescent spots indicates the presence of an extra copy of the chromosome identified by the probe; probes for several chromosomes are used simultaneously so that aneuploid sperm are distinguishable from diploid sperm.

Besides cytological observation, indirect evidence for chromosome aberrations is obtained in the mouse heritable translocation assay, which measures reduced fertility in the offspring of treated males (Russell and Shelby, 1985; Singer et al., 2006). This presumptive evidence of chromosomal rearrangements can be confirmed through cytogenetic analysis. Data from the mouse heritable translocation test in postmeiotic male germ cells have been used in an attempt to quantify human germ cell risk for ethylene oxide, a mutagen used as a fumigant, sterilizing agent, and monomer in chemical syntheses (Preston et al., 1995).

Dominant Lethal Mutations The mouse or rat dominant lethal assay (Adler et al., 1994; Singer et al., 2006) has offered an extensive database on the induction of genetic damage in mammalian germ cells. In the most commonly used version of the assay, males are treated on an acute or subchronic basis with the chemical of interest and then mated with virgin females at appropriate intervals. The females are necropsied during pregnancy so that embryonic mortality may be characterized and quantified. Most dominant lethal mutations, manifested as intrauterine deaths, are thought to arise from chromosomal anomalies.

Development of Testing Strategies

Concern about adverse effects of mutation on human health, principally carcinogenesis and the induction of transmissible damage in germ cells, has provided the impetus to identify environmental mutagens. Priorities must be set for testing because it is not feasible to conduct multiple tests of all chemicals to which people are exposed. Such factors as production volumes, intended uses, the extent of human exposure, environmental distribution, and effects that may be anticipated on the basis of chemical structure or previous testing must be considered in order to ensure that compounds with the greatest potential for adverse effects receive the most comprehensive study. The most obvious use of genetic toxicology assays is screening chemicals to detect mutagens, but they are also used to obtain information on mutagenic mechanisms and dose–responses that contribute to an evaluation of hazards and risk. Besides testing pure chemicals, environmental samples are tested because many mutagens exist in complex mixtures (DeMarini 1998; Ohe et al., 2003; White, 2004). The analysis of complex mixtures often requires a combination of mutagenicity assays and refined analytical methods (White, 2004; Hewitt and Marvin, 2005). Assessment of a chemical's genotoxicity requires data from well-characterized and adequately validated assays. Assays are said to be validated when they have been shown to perform reproducibly and reliably with many compounds from diverse chemical classes in several laboratories. An evaluation of test performance and interpretability, however, sometimes extends beyond determining whether the assay effectively detects the specific endpoint that it actually measures to whether it is predictive of other endpoints of interest. For example, there is great interest in the ability of mutagenicity tests, which do not measure carcinogenicity per se, to predict whether chemicals are carcinogens.

Mutagenicity testing, combined with an evaluation of chemical structure, has been found to identify a large proportion of trans-species, multiple-site carcinogens (Tennant and Ashby, 1991; Gold et al., 1993). In contrast, some carcinogens are not detected as mutagens. Putatively non-genotoxic carcinogens often give responses that are more specific with respect to species, sites, and conditions (Ashby and Paton, 1993; Gold et al., 1993). In predicting carcinogenicity, one should consider both the sensitivity and the specificity of an assay. Sensitivity refers to the proportion of carcinogens that are positive in the assay, whereas specificity is the proportion of non-carcinogens that are negative (Tennant et al., 1987; McGregor et al., 1999). Sensitivity and specificity both contribute to the predictive reliability of an assay. The commonly held view that deficiencies in the sensitivity or specificity of individual assays may be circumvented by using assays in complementary combinations called tiers or batteries has fallen into disfavor because, rather than offsetting each other's strengths and weaknesses, genetic toxicology assays are often consistent with one another (Tennant et al., 1987; Ashby and Tennant, 1991; Kim and Margolin, 1999). The specificity of in vitro assays decreased to such an extent that nearly 95% of all noncarcinogens tested were detected as positive in at least one of the three in vitro assays (Ames, mouse lymphoma forward mutation assay, and in vitro cytogenetics; Kirkland et al., 2005).

Strategies for testing have evolved over the last few decades, such that data from a few well-chosen assays are now considered sufficient for intended applications (MacGregor et al., 2000; EFSA, 2012; Bolognesi et al., 2017; Ji et al., 2017). Rather than trying to assemble extensive batteries of complementary assays, it is prudent to emphasize mechanistic considerations in choosing assays. The bacterial Ames (OECD TG 471, 1997) test has always been considered as the preferred starting point for mutagenicity assessment and it performed reliably with thousands of compounds in laboratories throughout the world; it affords reasonable sensitivity and relatively high specificity compared to in vitro mammalian cell mutagenicity tests to detect rodent carcinogens and in vivo mutagens (Kirkland et al., 2005; Ji et al., 2017). In cases where a material cannot be adequately tested in bacteria because of its excessive toxicity (e.g., certain antimicrobial agents), mammalian cell cultures can be used to investigate mutagenic effects. Beyond gene mutations,

one should evaluate damage at the chromosomal level with a mammalian in vitro or in vivo cytogenetic assays. The preferred in vitro subset of mutagenicity and genotoxicity tests for regulatory mutagenicity assessments include bacterial reverse mutation test (OECD TG 471, 1997) and in vitro mammalian cell gene mutation tests using *Hprt* or *xprt* genes (OECD TG 476, 2016) for gene mutations; alternatively in vitro mammalian cell gene mutation tests using *tk* gene (OECD TG 490, 2015) is used to detect both gene mutations and structural chromosomal aberrations (Ji et al., 2017). For the assessment of structural chromosomal aberrations either in vitro mammalian chromosomal aberration test (OECD TG 473, 2016) or in vitro mammalian cell micronucleus test (OECD TG 487, 2016) can be used; the latter test, in addition to structural chromosomal aberrations, provides information of numerical chromosomal aberrations (Ji et al., 2017). Typically, negative outcomes in the in vitro assays would not call for in vivo follow-up, unless the intended application or regulatory jurisdiction called for it (Ji et al., 2017). Cytogenetic and transgenic mutation assays in rodents are especially useful for validating positive in vitro outcomes because they combine a well-validated genetic assay with mammalian pharmacodynamics and metabolism. The other assays in Table 9-1 offer an extensive database on chemical mutagenesis (i.e., *Drosophila* SLRL), a unique genetic endpoint (i.e., aneuploidy; mitotic recombination), applicability to diverse organisms and tissues (i.e., DNA damage assays, such as the comet assay), or special importance in the assessment of genetic risk (i.e., germ cell assays). The more extensive listing of assays in Table 9-2 provides references that can be helpful in interpreting genetic toxicology data that can be found in the scientific literature.

HUMAN POPULATION MONITORING

For cancer risk assessment considerations, the human data utilized most frequently, in the absence of epidemiologic data, are those collected from genotoxicity/mutagenicity assessments in human populations. For this purpose, the studies conducted most frequently are for chromosome aberrations, micronuclei, mutations (for several loci), and SCEs in peripheral lymphocytes. Cytogenetic alterations have also been assessed in a small number of bone marrow samples. Mutations at the *HPRT* locus have been assessed in peripheral lymphocytes. Glycophorin A variants have been studied in red blood cells. In the future, the *Pig-a* mutation assay using peripheral blood lymphocytes will likely gain popularity for human biomonitoring because of its technical simplicity.

An important component of any population monitoring study is the selection of the study groups, namely those individuals who are potentially exposed and the matched unexposed controls. The size of each study group should be sufficiently large to avoid any confounder having undue influence. It is also important to have a reliable measure to ascertain exposure(s). Certain characteristics should be matched among exposed and unexposed groups. These include age, sex, smoking status, and general dietary features. Certain characteristics are exclusionary, namely current or recent medication, radiation exposure, and certain illnesses. It is possible to develop a lengthy list of additional possible confounders of response that would make the selection of suitable study groups very difficult indeed. Study groups of 20 or more individuals can be used as a reasonable substitute for exact matching because confounders will be less influential on chromosome alteration or mutation frequency in larger groups (discussed in Au et al., 1998; Battershill et al., 2008). In some instances, it might be informative to compare exposed groups with a historical control, as well as to a concurrent control.

The magnitude of different known confounders varies considerably among studies, based in part on the size of the study populations. Some general indication of the magnitude of the effects of age and smoking status on the frequencies of chromosome aberrations and SCE is presented to illustrate the importance of accounting for confounders in the design of a population monitoring study. The comparisons presented are for large studies only. For chromosome aberrations, the frequency of aberrations has been reported in one large study to be about 50% higher in smokers (l.5 aberrations per 100 cells in smokers vs. 1.0 per 100 cells in the nonsmokers) (Galloway et al., 1986) and in another no difference between smokers and nonsmokers (Bender et al., 1988a, 1988b). The complete data set has been reviewed by Au et al. (1998). In general, the frequency of SCE is increased by about one SCE per cell in smokers compared with nonsmokers (Bender et al., 1988a, 1988b; Barale et al., 1998). The study by Barale et al. (1998) also reported a dose-response association between SCE frequency and smoking level. The differences among these studies might well be accounted for by differences among confounders in the respective groups, but it is virtually impossible to correct for these in this type of study.

Chromosome aberrations are among the most thoroughly studied effects of IR exposure (Awa, 1997). IR-induced chromosome aberrations include intrachromosomal exchanges that produce ring chromosomes or inversions, and interchromosomal exchanges, involving two chromosomes that produce dicentrics or translocations. A wide variability of the frequency of cells with chromosome aberrations between Hiroshima and Nagasaki atomic bomb survivors, different dose–response relationships in the two cities, significant effects of both time of assay, and age at the time of exposure were observed (Stram et al., 1993; Awa, 1997). Japanese atomic bomb survivor studies have demonstrated that translocation frequency is useful for the evaluation of IR dosimetry (Awa, 1997). Likewise, Chernobyl survivors exposed to very high IR doses showed complex chromosomal aberrations, with many dicentrics and reciprocal translocations (Awa, 1997).

The frequency of chromosome aberrations, particularly chromosome-type (reciprocal) exchanges, has been shown to increase with age of subject (Tucker and Moore, 1996). Galloway et al. (1986) reported an increase from 0.8 per 100 cells at about 25 years of age to about 1.5 at 60. Bender et al. (1988a, 1988b) reported an increase with age only for chromosome-type dicentric aberrations, but the increase over a broad age range was small and just statistically significant. Ramsey et al. (1995), using chromosome painting techniques, reported that individuals 50 years and older had frequencies of stable aberrations, dicentrics, and acentric fragments that were 10.6-, 3.3-, and 2.9-fold, respectively, greater than the frequency in cord bloods. Bender et al. (1988a, 1988b) did not find an increase in SCE frequency with the increasing age of the subject. The differences among the results from these large control studies emphasize the difficulty of adequately accounting for confounders (age and smoking presented here) when only a small control group is used, as is frequently the case.

Similar sources of variation have been identified for the monitoring of individuals for *HPRT* mutations. The data are reviewed in detail by Albertini and Hayes (1997). There is less information on sources of variation of glycophorin A (GPA) variants, although quite considerable inter-individual variation exists (reviewed in Cole and Skopek, 1994; Kyoizumi et al., 2005).

For cytogenetic assays (chromosome aberrations, SCEs, and micronuclei) the alterations are produced as a consequence of errors of DNA replication, as discussed in previous sections. From the nature of the alterations, assessed in traditional cytogenetic assays in which nontransmissible alterations are analyzed, it can be

established that these alterations were produced at the first in vitro S phase. Irrespective of the duration of exposure, the frequency of cytogenetic alterations will be proportional to that fraction of the DNA damage that remains at the time of in vitro DNA replication. All the DNA damage induced by potent clastogens that results in chromosome alterations is repaired within a relatively short time after exposure for G_0 human lymphocytes. Thus, for chronic exposures the lymphocyte cytogenetic assay as typically conducted is insensitive.

Reciprocal translocations using FISH methods can also be analyzed (reviewed in Awa, 1997; Tucker et al., 1997; Beskid et al., 2006; Kleinerman et al., 2006). The stable chromosome aberrations observed in peripheral lymphocytes exposed in vivo are produced in the hematopoietic stem cells or other precursor cells of the peripheral lymphocyte pool, but assessed following in vitro culture. To date, population cytogenetic monitoring studies involving the analysis of reciprocal translocations in chemically exposed individuals or radiation-exposed individuals have been rarely conducted (Lucas et al., 1992; Director et al., 1998; Smith et al., 1998; Kleinerman et al., 2006; Donner et al., 2010).

Another factor that certainly affects the utility of population monitoring data with reciprocal translocations using FISH is that the frequency of reciprocal translocations increases significantly with increasing age (Ramsey et al., 1995), but to a lesser extent for nontransmissible aberrations (Bender et al., 1988a, 1988b). Ramsey et al. (1995) provided data on the influence of other confounders on the frequency of reciprocal translocations in human groups. These confounders include smoking, consumption of diet drinks and/or diet sweeteners, exposure to asbestos or coal products, and having a previous major illness. This reemphasizes the point that the selection of study groups and accounting for confounders is essential for human population cytogenetic monitoring studies to be of utility.

Thus, very few of the published studies of cytogenetic population monitoring for individuals have analyzed the appropriate endpoint for detecting the genetic effects of long-term exposure to chemicals. It is quite surprising that positive responses have been reported for increases in unstable, chromatid aberrations because these are nontransmissible, and as noted above are induced at the first in vitro S phase. This anomaly is especially concerning when positive responses at very low levels of exposure are reported (reviewed for ethylene oxide in Preston, 1999b).

The HPRT mutation assay can assess the frequency of induced mutations in stem cells or other precursor cells because a proportion of the mutations are induced as nonlethal events. The transmissible proportion will be greater for chemicals that do not induce large deletions; this will include the majority of nonradiomimetic chemicals. Induction of mutations in lymphocyte precursor cells will lead to clonal expansion of mutations in the peripheral pool. However, assessment of the T-cell antigen receptor status of the mutant clones permits a correction for clonal expansion. The population of cells derived from any particular stem cell has a unique antigen receptor status (Albertini and Hayes, 1997). The GPA assay can similarly be used for the assessment of chronic exposures or for estimating exposures at some long time after exposure (Albertini and Hayes, 1997). The predictive value of the assay for adverse health outcome appears to be limited, but it can provide an estimate of exposure.

The potential for cytogenetic endpoints being predictive of relative cancer risk has been addressed in recent reports from the European Study Group on Cytogenetic Biomarkers and Health (Hagmar et al., 1998a, 1998b; Bonassi et al., 2004; Norppa et al., 2006). The groups selected for cytogenetic studies consisted of individuals with reported occupational exposure and unexposed controls. The association between cancer and the frequency of unstable chromosome aberrations in the study groups was not based on exposure status, but rather on the relative frequency of chromosome aberrations, namely, low (1 to 33 percentiles), medium (34 to 66 percentiles), and high (67 to 100 percentiles). In general, the higher the relative frequency of unstable aberrations, the greater the risk of cancer death for all tumors combined. The authors make it clear that there is insufficient information on exposure for it to be used as a predictor of cancer development. In fact, the data indicate that individuals with higher frequencies of chromosome aberrations for whatever reason (genetic or environmental) are *as a group* at greater risk of dying from cancer. This is very different from concluding that exposures to mutagens that result in a higher frequency of chromosome aberrations in peripheral lymphocytes leads to an increased risk of cancer, especially for specific tumor types. The relevance of exposure to mutagenic chemicals in these studies by Hagmar et al. (1998a, 1998b) is uncertain because there was no association between increased SCE frequencies, which may be indicative of higher exposure levels, and increased cancer mortality.

This latter concern was addressed by the same group (Bonassi et al., 2000) in a more recent study. The study again showed that there was a significantly increased risk for subjects with a high level of chromosome aberrations compared to those with a low level in both Nordic and Italian cohorts. Of particular relevance to risk assessment was the observation that the relationships were not affected by the inclusion of occupational exposure level or smoking. The risk for high versus low levels of chromosome aberrations was similar in individuals heavily exposed to carcinogens and in those who had never, to their knowledge, been exposed to any specific environmental carcinogen. These data highlight the need to use caution when considering the relevance of chromosome aberration data from human biomonitoring studies in cancer risk assessment.

NEW APPROACHES FOR GENETIC TOXICOLOGY

In the last 20 or so years, the field of genetic toxicology has moved into the molecular and computational era. The potential for advances in our understanding of basic cellular processes and how they can be perturbed is enormous. The ability to manipulate and characterize DNA, RNA, and proteins has been at the root of this advance in knowledge. New understanding in biological mechanism and mode of action (MOA), along with new high-content and high-throughput approaches, and increasingly sensitive analytical methods, bring new information into the field of genetic toxicology and the quantitative risk assessment processes for DNA-reactive chemicals (MacGregor et al., 2015a, 2015b; Klapacz et al., 2016). The introduction of new high-throughput screening to assess various biomarker parameters, such as DNA damage to evaluate genotoxicity, offers rapid, cost-effective, and nonlabor-intensive screening approaches (Ranganatha et al., 2016). A clear focus on molecular and biological approaches to defining and understanding consequences of DNA damage at the cellular level fits well with the 2007 NRC report, "Toxicity Testing in the 21st Century: A Vision and a Strategy" that envisions a future in which all routine testing will use cell-based in vitro assays of toxicity pathways (NRC, 2007b; Krewski et al., 2010). It is now becoming understood that complex interactions within a particular DNA repair pathway, as well as interplay between different DNA repair and DDR pathways exist that counteract the effects of ever-present background DNA damage. Together, these pathways appear sufficient to counteract mutation at low exposures/doses and/or the propagation of cells harboring significant DNA damage at least for well-studied

DNA-reactive classes (Klapacz et al., 2016). Hence, the examination of key cellular, mechanistic responses should be integrated into the designs of the mutagenic MOA studies and risk characterization processes for DNA-reactive chemicals.

Advances in Cytogenetics

Until quite recently, the analysis of chromosome alterations relied on conventional chromosome staining with DNA stains such as Giemsa or on the process of chromosome banding. Both approaches require considerable expenditure of time and a rather high level of expertise. However, chromosome banding does allow for the assessment of transmissible aberrations such as reciprocal translocations and inversions with a fairly high degree of accuracy. Knowing the induction frequency of such aberrations is very important, given that they are generally not lethal to the cell and constitute by far the major class observed in inherited genetic defects and a significant fraction of the alterations observed in tumors. In addition, because stable aberrations are transmissible from parent to daughter cell, they represent accumulated effects of chronic exposures. The more readily analyzed, but cell-lethal, nontransmissible aberrations such as dicentrics and deletions reflect only recent exposures and then only when analyzed at the first division after exposure. A more detailed discussion of these factors can be found in Preston (1999b).

There is an extensive literature on the use of FISH for tumors and in gene mapping but less on its utility for genetic toxicology studies, especially the assessment of stable chromosome aberrations at long periods after exposure or after long-term exposures. Three particular studies do, however, serve to exemplify the use of FISH in genetic toxicology.

Lucas et al. (1992) demonstrated that stable chromosomal aberrations could be detected in individuals decades after exposure to atomic bombs in Japan. How these frequencies relate to frequencies at the time of exposure is not known with any certainty, given the fact that induced frequencies were not measured because appropriate techniques were not available at that time.

Studies by Tucker et al. (1997, 2005) provided some assessment of the utility of FISH karyotyping for the analysis of radiation-induced, stable chromosome alterations at various times after exposure. The frequency of reciprocal translocations induced by γ-rays in rat peripheral lymphocytes decreased with time after exposure, reaching a plateau at 4 days that was 55% to 65% of the induced frequency and with a dose dependency (Tucker et al., 1997). Similar results were obtained for human samples (Tucker et al., 2005). These results suggest that reciprocal translocations fall into two classes, stable and unstable (cell-lethal). It is quite possible that these "unstable" translocations are lost because of the presence of other cell-lethal damage in the same cell. Additional work is required to clarify this conclusion and to extend the studies to the effects of chemicals. In addition, a recent study by Tucker and Luckinbill (2011) demonstrated how FISH translocation analysis could be used to detect extremely low doses of ionizing radiation—a few cGy per year. Such analysis could be used to estimate responses at very low doses for utility in risk assessments at similarly low doses.

FISH methods have also allowed for an accurate and sensitive assessment of chromosomal alterations present in tumors. The particular advance that makes this assessment feasible is known as comparative genomic hybridization (CGH) (Kallioniemi et al., 1992). CGH results in the ability to identify the role of chromosomal structural and numerical alterations in tumor development. The genomic instability present in all tumor types appears to have a specific genetic basis, as shown elegantly for colon cancer by Vogelstein and colleagues (Cahill et al., 1998). For CGH, tumor and control DNAs are differentially labeled with fluorescence probes and co-hybridized to normal metaphase chromosome preparations. The ratio of the fluorescence intensities of hybridized tumor and control DNA indicates regions of normal genomic content as well as those regions that are over- or underrepresented in tumors. The CGH method is being adapted for automated screening approaches using biochips (Solinas-Toldo et al., 1997; Hosoya et al., 2006). Assessing genetic alterations such as specific gene deletions in single metastatic tumor cells is feasible using a slightly different but complementary approach (Pack et al., 1997, 2005).

The types of FISH approaches described here undoubtedly indicate the direction in which cytogenetic analysis will proceed. The types of data collected will affect our understanding of how tumors develop. Data on the dose–response characteristics for a specific chromosomal alteration as a proximate marker of cancer can enhance the cancer risk assessment process by describing effects of low exposures that are below those for which tumor incidence can be reliably assessed. Cytogenetic data of the types described above can also improve extrapolation from data generated with laboratory animals to humans.

Molecular Analysis of Mutations and Gene Expression

With the advent of molecular biology techniques, the exact basis of a mutation at the level of the DNA sequence can be established. In many cases, the genetic basis of human disease can be determined even though human genes have long DNA sequences and a complex genomic arrangement. Molecular biology techniques have also enabled a distinction to be made between background mutations and those induced by specific agents. The latter observations are addressed by analyzing the mutational spectra in target genes in laboratory organisms and in humans (DeMarini, 2000; Hemminki and Thilly, 2004). For reasons of inherent sensitivity of available methods, the genes analyzed for mutations are ones for which mutated forms can be selected. The confounding factor of many normal cells, which far outnumber a few mutant cells in an exposed cellular population, can be removed by mutant selection approaches. Methods to overcome the drawback of only being able to study selectable genes have been developed, and particular ones such as ligation-mediated PCR are close to the required sensitivity level (Albertini and Hayes, 1997; Makrigiorgos, 2004; Yeh et al., 2006). For example, COLD-PCR (co-amplification at lower denaturation temperature-PCR) was developed to selectively amplify minority alleles from mixtures of wild-type and mutation-containing sequences (Li and Makrigiorgos, 2009).

A giant step forward in the ability to detect and characterize mutations at both the DNA and RNA level has been provided by the development of chip technology (Southern, 1996), array-based assay systems (Wodicka et al., 1997), and next-generation high-throughput DNA sequencing technologies at the whole genome level in a very short period of time (Greenman et al., 2007; Watson et al., 2013; Yauk et al., 2015; Du et al., 2017). With hybridization of test DNAs to oligonucleotide arrays, specific genetic alterations or their cellular consequences can be determined rapidly and automatically (Houlston and Peto, 2004; Vissers et al., 2005). Genome-wide gene expression microarray technologies now allow the measurement of changes in expression of thousands of genes at one time (Harrington et al., 2000; Elvidge, 2006; Blencowe et al., 2009). There are parallel efforts in the area of proteomics and metabolomics whereby changes in a broad range of cellular proteins

can be assessed in response to endogenous or exogenous factors, potentially leading to the development of biomarkers of effect (Aebersold et al., 2005; Robertson, 2005; Griffin, 2006; McGregor and De Souza, 2006). The biggest hurdle currently is the relative paucity of sequence data available for the world of proteins and their multiple posttranslational modifications. Certainly progress is rapid, and so methodologies akin to gene expression assessment are likely to be close at hand (Xie et al., 2011). The sensitivity of next-generation sequencing protocols is rapidly increasing and the costs are gradually coming down. Such techniques have been used to characterize the genetic alterations in a large number of tumor types, allowing for new insight and revealing unanticipated complexities in the patterns of somatic alterations in cancers (Greenman et al., 2007; Stratton et al., 2009; Watson et al., 2013). Overall, the current potential for assessing specific cellular changes following chemical exposure is enormous.

The move in the field of genetic toxicology is away from the "yes/no" approach to hazard identification and much more toward a mechanistic understanding of how a chemical or physical agent can produce adverse cellular and tissue responses. In turn, such knowledge can be used for the development of informative bioindicators representing the key events along the pathway from initial interactions with cells to adverse outcome (Jarabek et al., 2009). The move is clearly toward analysis at the whole genome level and away from single gene responses. The challenges are apparent and the solutions are being identified at a rapid pace. In a recent publication, Dearfield et al. (2017) laid the foundation for the next generation testing strategy to assess genomic damage. This strategy envisions a broader focus for assessing genomic damage instead of primarily fixating on carcinogen prediction.

CONCLUSIONS

The field of genetic toxicology has had an overall life of about 70 years and has undergone several rebirths during this period. Genetic toxicology began as a basic research field with demonstrations that ionizing radiation and chemicals could induce mutations and chromosome alterations in plant, insect, and mammalian cells. The development of a broad range of short-term assays for genotoxicity served to identify many mutagens and address the relationship between mutagens and cancer-causing agents, or carcinogens. The inevitable failure of the assays to be completely predictive resulted in the identification of nongenotoxic carcinogens. In the 1980s, genetic toxicology began to move toward providing insights into a better understanding of the mutagenic mechanisms underlying carcinogenicity and heritable effects. In recent years, genetic toxicology studies began to turn away from hazard identification alone and move toward risk-based testing (Gollapudi, 2017).

Genetic toxicology has begun to take advantage of the knowledge that cancer is a genetic disease with multiple steps, many of which require a mutation. The ability to distinguish between background and induced mutations, in some cases, can be achieved by mutation analysis at the level of DNA sequence. Next-generation sequencing technologies have allowed such whole genome mutation analysis to be accomplished in a very short time. Key cellular processes related to mutagenesis have been identified, including multiple pathways of DNA repair, cell cycle controls, and the role of checkpoints in ensuring that the cell cycle does not proceed until the DNA and specific cellular structures are checked for fidelity. These observations have enhanced our knowledge of the importance of genotype in susceptibility to cancer. Recent developments in genetic toxicology have greatly improved our understanding of basic cellular processes and alterations that can affect the integrity of the genetic material and its functions. The incorporation of key cellular, mechanistic information should be integrated into the designs of the MOA studies of various types of DNA-reactive chemicals and applied to their risk assessment processes. The ability to detect and analyze mutations in mammalian germ cells continues to improve and can contribute to a better appreciation for the long-term consequences of mutagenesis in human populations. Improvements in the qualitative assessment of mutation in somatic cells and germ cells have been paralleled by advances in the ability to assess genetic alterations quantitatively, especially in ways that enhance the cancer and genetic risk assessment process (Preston, 2005; Gollapudi, 2017). These new approaches will reduce overall uncertainty in the process, specifically for risk characterization and uncertainties surrounding exposures at environmentally relevant concentrations (Table 9-4).

HISTORY OF TERATOLOGY

Teratology as an empirical science has been around for millennia and encompasses the study of abnormal structural development. Conjoined twins have been depicted in marble statuary dating to 6500 BC (Warkany, 1983), and Egyptian wall paintings of human cleft palate and achondroplasia date to 5000 years ago. The origin of mythological creatures including the Cyclops and sirens may have been observations of malformed infants (Thompson, 1930; Warkany, 1977). Hippocrates and Aristotle thought that physical agents such as uterine trauma or pressure could cause birth defects. Aristotle also believed that maternal impressions and emotions could affect the developing fetus, and advised pregnant women to gaze at beautiful art to enhance their child's beauty. This idea is historically present in diverse cultures, and we now understand that maternal stress or depression during pregnancy can be deleterious (Dunkel Schetter and Tanner, 2012).

In the 16th and 17th centuries, scientific theories of causation of birth defects emerged. In 1651, William Harvey expounded the theory of developmental arrest, which posited that malformations resulted from incomplete structural development. An example was "harelip," a congenital malformation in humans that represents a normal but usually transient embryonic stage. In the early 19th century, Saint-Hilaire produced malformed chick embryos by

subjecting eggs to physical trauma or toxic exposures. Later in the 19th century, Dareste produced various malformations in chick embryos using chemical and physical agents including heat shock. Dareste found that timing was more critical than the type of insult in influencing the type of defect that resulted (Dareste, 1877, 1891). Many of the great embryologists of the 19th and 20th centuries, including Loeb, Morgan, Driesch, Spemann, and Hertwig, performed teratological experiments using various physical and chemical probes to deduce principles of normal development.

With the rediscovery of Mendel's laws in 1900, it was accepted that some birth defects were hereditary. Bateson (1894) studied animal variations as a means to elucidate evolution, suggesting that inheritance of variations was a means of speciation. He described human birth defects including polydactyly and syndactyly, supernumerary cervical and thoracic ribs, duplicated appendages, and fused kidneys. A genetic basis of birth defects was further supported by studies of inborn errors of metabolism in the early 20th century.

In the 1920s through 1940s, a variety of environmental conditions and exposures were proven to perturb development in avian, reptilian, fish, and amphibian species. Yet, at that time, mammalian development was thought to be protected from environmental conditions by the mother's body. That idea was refuted when Hale (1935) produced anophthalmia, cleft palate, and other malformations in offspring of pigs by feeding a vitamin A deficient diet. Beginning in 1940, Josef Warkany and co-workers performed a series of experiments demonstrating that maternal dietary deficiencies and other environmental factors could perturb intrauterine development in rats (Warkany and Nelson, 1940; Warkany and Schraffenberger, 1944; Warkany, 1945; Wilson et al., 1953). Since these early studies, many other chemical and physical agents have been demonstrated to cause malformations in mammals (see Warkany [1965]).

HUMAN TERATOGENS AND DEVELOPMENTAL TOXICANTS

With the development of highly sensitive tests that can detect pregnancies shortly after fertilization, recognized pregnancy loss increased to as much as 60% to 70%. Estimates of adverse outcomes include postimplantation pregnancy loss, 31%; major birth defects, 2% to 3% at birth and increasing to 6% to 7% at 1 year with continuing diagnoses; minor birth defects, 14%; low birth weight, 7%; infant mortality (prior to 1 year of age), 1.4%; and abnormal neurological function, 16% to 17% (Schardein, 2000). Brent and Beckman (1990) attributed 15% to 25% of human birth defects to genetic causes, 4% to maternal conditions, 3% to maternal infections, 1% to 2% to *deformations* (e.g., mechanical damage to normally formed structures, such as umbilical cord limb amputations), <1% to chemicals and other environmental influences, and 65% to unknown causes. These estimates are similar to those suggested by Wilson (1977). Regardless of etiology, the sum total represents a significant health burden in light of the over 4 million births annually in the United States.

Schardein (2000) estimated that over 4100 chemicals had been tested in animals for teratogenicity by that time, a third of which were shown to be non-teratogenic, 7% clearly teratogenic in more than one species, 18% "probably" teratogenic (limited testing or positive in majority of species tested) and 9% producing equivocal results. A much smaller number, about 35 to 40 chemicals, chemical classes, or conditions (Table 10-1), have been documented to be developmentally toxic in humans (Schardein and Keller, 1989; Shepard and Lemire, 2004).

How does one determine that a drug, chemical, or other agent, is a likely human teratogen? Criteria for proof of human teratogenicity, based on several sources, have been assembled by Tom Shepard (Shepard, 1994) (Table 10-2), although he stated at that time that not all human teratogens will fit these exact criteria. Shepard also described two modes of establishing an exposure as a human teratogen. The first is the rare malformation/rare exposure or case report method, sometimes referred to as the astute clinician approach (Carey et al., 2009) and the second is the epidemiological method; these have been compared and contrasted (Shepard, 1991). Examples of the case report approach include rubella, thalidomide, and diethylstilbestrol, while teratogens uncovered using the epidemiological approach include more common exposures with more common outcomes, perhaps including, for example, orofacial clefts caused by maternal smoking, or neural tube defects caused by valproic acid. These teratogens are among those summarized below. In a more contemporary example, Rasmussen et al. (2016) used Shepard's criteria to determine that the Zika virus infection during

Table 10-1

Human Developmental Toxicants

Radiation
- Atomic fallout
- Radioiodine
- Therapeutic radiation

Infections
- Cytomegalovirus
- Herpes simplex virus I and II
- Parvovirus B-19 (erythema infectiosum)
- Rubella virus
- Syphilis
- Toxoplasmosis
- Varicella virus
- Venezuelan equine encephalitis virus

Maternal trauma and metabolic imbalances
- Alcoholism
- Amniocentesis, early
- Chorionic villus sampling (before day 60)
- Cretinism
- Diabetes
- Folic acid deficiency
- Hyperthermia
- Phenylketonuria
- Rheumatic disease and congenital heart block
- Sjögren syndrome
- Virilizing tumors

Drugs and chemicals
- Aminoglycosides
- Androgenic hormones
- Angiotensin converting enzyme inhibitors: captopril, enalapril
- Angiotensin receptor antagonists: sartans
- Anticonvulsants: diphenylhydantoin, trimethadione, valproic acid, carbamazepine
- Busulfan
- Carbon monoxide
- Chlorambucil
- Cocaine
- Coumarins
- Cyclophosphamide
- Cytarabine
- Diethylstilbestrol
- Danazol
- Ergotamine
- Ethanol
- Ethylene oxide
- Fluconazole
- Folate antagonists: aminopterin, methotrexate
- Iodides
- Lead
- Lithium
- Mercury, organic
- Methimazole
- Methylene blue
- Misoprostal
- Penicillamine
- Polychlorobiphenyls
- Quinine (high dose)
- Retinoids: isotretinoin, etretinate, acitretin
- Tetracyclines
- Thalidomide
- Tobacco smoke
- Toluene
- Vitamin A (high dose)

Table 10-2

Shepard's Criteria for Proof of Human Teratogenicity

1. Proven exposure to agent at critical time(s) in prenatal development.
2. Consistent findings by greater or equal to two high-quality epidemiological studies; prospective studies, if possible; relative risk greater or equal to 6.
3. Careful delineation of the clinical cases. A specific defect or syndrome is helpful.
4. Rare exposure associated with rare defect. Probably three or more cases.
5. Teratogenicity in experimental animal studies important but not essential.
6. The association should make biological sense.
7. Proof in an experimental system that the agent acts in an unaltered state.

Items 1 to 3 (epidemiological approach) or 1, 3, and 4 (rare exposure/rare defect approach) are essential; items 5 to 7 are helpful but not essential.

SOURCE: Shepard (1994).

pregnancy is a human teratogen, causing microcephaly and other brain and eye malformations.

Maternal Rubella Infection

Gregg (1941) reported the first recognized case of widespread human malformations, linking an epidemic of rubella virus infection in Australia to congenital malformations including eye, heart, and ear defects, and mental retardation. Heart and eye defects were associated with maternal infection in the first 2 months of pregnancy, while hearing and speech defects and mental retardation occurred with infection in the third month (Sever, 1967). In the United States alone, it was estimated that 20,000 children were adversely affected (Cooper and Krugman, 1966). Rubella is now uncommon in developed countries due to widespread vaccination, but there have been recent outbreaks in developing countries (DeSantis et al., 2006; Chandy et al., 2011) and reported cases in developed countries as well (Vauloup-Fellous et al., 2010).

Thalidomide

Thalidomide was first marketed in Europe in 1956 and was used throughout much of the world as a sleep aid and treatment for morning sickness. There were a few reports of peripheral neuritis attributed to the drug with long-term use for up to 18 months (Fullerton and Kermer, 1961). In 1960, a striking increase in newborns with rare limb malformations was recorded in West Germany. The affected individuals had amelia (absence of the limbs) or various degrees of phocomelia (reduction of the long bones of the limbs). Congenital cardiac, ocular, otic, intestinal, and renal anomalies were also reported. In 1961, Lenz and McBride, working independently in Germany and Australia, respectively, identified thalidomide as the causative agent (McBride, 1961; Lenz, 1961, 1963). Amelia and phocomelia are rare malformations; the university clinic in Hamburg reported no cases of phocomelia between 1940 and 1959, 1 case in 1959, 30 cases in 1960, and 154 cases in 1961 (Taussig, 1962). The rarity of the malformations was a key factor in recognizing the epidemic. Thalidomide was withdrawn in November 1961, and case reports ended in mid-1962. Estimates of the total number of affected infants worldwide during this period range from 5840 (Lenz, 1988) to over 10,000 in 46 countries (Bartlett et al., 2004). Due to concerns regarding the severity of the peripheral neuropathy and subsequent questions with regard to safety in pregnancy, the U.S. Food and Drug Administration (FDA) did not approve thalidomide for use in the United States. Dr Frances Kelsey, a new FDA staff member at that time, was key to keeping the drug off the market in the United States. She later received the highest civilian honor in the United States, the medal for Distinguished Federal Civilian Service, from President John F. Kennedy, for her diligence in protecting the country. In part as a response to the thalidomide catastrophe, many countries began developing regulatory requirements for evaluating the effects of drugs during pregnancy using laboratory animals (Stirling et al., 1997). In the United States, the Segment I, II, and III testing protocols were promulgated by the FDA in 1966 (Kelsey, 1988). Current regulatory testing guidelines for developmental toxicity are discussed later in this chapter.

Thalidomide presents a variable pattern of developmental toxicity in at least 19 species in which it has been tested. Increased embryonic loss has been observed in some studies in rats, while generally no effects were reported in studies with most mouse strains. Effects more or less similar to those observed in humans have been reported for several rabbit strains and in eight of nine nonhuman primate species tested. The teratogenic dosage ranges from about 1 to 100 mg/kg, with humans being most sensitive (Schardein, 1993). Research to elucidate species and strain differences in response to thalidomide has met with limited success. Stephens (1988) summarized 24 putative mechanisms including biochemical alterations involving vitamin B, glutamic acid, acylation, nucleic acids, and oxidative phosphorylation; cellular mechanisms including cell death and cell–cell interactions; and inhibition of nerve and blood vessel outgrowth. More recent hypotheses include effects on angiogenesis (D'Amato et al., 1994; Joussen et al., 1999; Sauer et al., 2000; Stephens et al., 2000; Therapontos et al., 2009), integrins (Neubert et al., 1996), oxidative DNA damage (Parman et al., 1999), TNF-α inhibition (Argiles et al., 1998), growth factor antagonism (Stephens et al., 1998; Stephens and Fillmore, 2000), effects on redox status (Hansen et al., 1999), and inhibition of ubiquitin-mediated protein degradation (Ito et al., 2011; Ito and Handa, 2012).

Wells and colleagues (Parman et al., 1999) compared the effects of thalidomide in the pregnant mouse (a resistant species) and the pregnant rabbit (a sensitive species) and demonstrated increased DNA oxidation in rabbit, but not in mouse embryos. Pretreatment of pregnant rabbits with alpha-phenyl-*N*-*t*-butylnitrone, a free-radical scavenging agent, lowered thalidomide-induced embryonal DNA oxidation by 73%, and abolished almost all of the teratogenic effects. These results suggest that, in the sensitive rabbit, thalidomide is activated to a free-radical intermediate that is key to its teratogenicity. Hansen et al. (2002, 2004) have provided evidence that limb defects induced by thalidomide are due to altered expression of genes critical for limb outgrowth. They have demonstrated a shift in redox potential that reduces binding of a key transcription factor, NF-κB, to its response element in DNA. Binding of NF-κB is required for the normal expression of the genes *twist* and *FGF-10* in the mesenchyme and *FGF-8* in the apical ectodermal ridge of the developing limb. Inhibition of the expression of these genes by thalidomide could be predicted to cause the limb defects seen in sensitive species. Differences in redox regulation and consequent effects on redox-sensitive NF-κB may underlie species differences in teratogenicity of thalidomide.

Thalidomide may see expanded use in diseases including dermatological disorders, arthritis, multiple myeloma, diabetic retinopathy, and macular degeneration (Adler, 1994; Calabrese and Fleischer, 2000; Schwab and Jagannath, 2006; Chen et al., 2010).

Thalidomide has been approved by the FDA for inflammatory complications of Hansen's disease (leprosy) and multiple myeloma. Sadly, new cases of thalidomide embryopathy have occurred in Brazil and elsewhere consequent to its use there for leprosy and sharing of the drug by those unaware of its hazard (Vianna et al., 2013). To prevent exposure during pregnancy, the drug is only available under the Thalidomid Risk Evaluation and Mitigation Strategy (REMS), which requires certification of prescribers, patient counseling, provision of contraception, pregnancy testing, and pharmacy certification (www.thalidomidrems.com/about.html).

Ethanol/Alcoholism

The fetal alcohol syndrome (FAS) was first described by Jones and Smith in the early 1970s (Jones and Smith, 1973; Jones et al., 1973). There has since been a clear recognition and acceptance of alcohol's developmental toxicity, documented in hundreds of clinical, epidemiologic, and experimental studies of ethanol exposure during development, revealing a still broadening array of effects of alcohol on development (for reviews, see Jones [2011], Hoyme et al. [2016], Lunde et al. [2016], and McQuire et al. [2016]).

The FAS includes craniofacial dysmorphology, growth retardation, and psychomotor and intellectual deficiencies (Abel, 1982, 2006; Jones, 2011). The IQ of FAS children has been reported to average 68 (Streissguth et al., 1991a, 1991b). The molecular mechanisms underlying FAS are still poorly understood, and the possible molecular and cellular targets are many (e.g., Sulik, 2005; Smith 2010; Zeisel, 2011). Most recently, epigenetic effects of alcohol exposure during prenatal development have been reported, including effects on DNA methylation (Laufer et al., 2017) and histone modifications (Chater-Diehl et al., 2017).

Full-blown FAS has been observed primarily in children born to alcoholic mothers, and among alcoholics the incidence of FAS has been estimated at 25 per 1000 pregnancies (Abel, 1984). Estimates of the level of maternal ethanol consumption associated with FAS are a minimum of 3 to 4 oz of alcohol per day (Clarren et al., 1987; Ernhart et al., 1987). However, FAS represents the extreme end of a wide range of effects of developmental alcohol exposure now termed fetal alcohol spectrum disorders (FASD) (Koren et al., 2003; Sokol et al., 2003; Manning and Hoyme, 2007; Hellemans et al., 2010). After adjusting for smoking, gestational age, maternal height, age, parity, and sex of the child, Little (1977) found, in 800 women studied prospectively, that each ounce of ethanol consumed per day during late pregnancy corresponded to a 160-g decrease in birth weight. Streissguth et al. (1994a, 1994b), in a longitudinal prospective study of 462 children, found that the number of drinks during pregnancy was the strongest predictor of adverse effects on offspring attention, short-term memory, and performance on standardized tests. Streissguth and co-workers have also reported that prenatal alcohol exposure was associated with alcohol drinking problems at age twenty-one (Baer et al., 2003). Later life vulnerability to stress, depression, and anxiety disorders after in utero alcohol exposure has been reviewed (Hellemans et al., 2010). For reviews of the neurotoxic effects of developmental ethanol exposure, see a special issue of *Neuropsychology Review* (21(2): June 2011).

Mouse models of the FAS have been developed over the years, beginning with a model in which female mice were fed a liquid diet containing 15% to 35% ethanol-derived calories prior to and during pregnancy (Chernoff, 1977). Injection of ethanol to pregnant C57Bl/6J mice during the time that embryos are undergoing *gastrulation* (Sulik et al., 1981; Sulik and Johnston, 1983) has been used to study the etiology and pathogenesis of the craniofacial effects seen in FAS. Fetuses of mice exposed to ethanol in this manner exhibit features of FAS including microcephaly, microphthalmia, short palpebral fissures, deficiencies of the philtral region, and a long upper lip. Increased apoptosis in sensitive cell populations is a common finding in embryos of treated dams (Kotch and Sulik, 1992; Sulik, 2005; Smith, 2010).

Diethylstilbestrol

A synthetic nonsteroidal estrogen, diethylstilbestrol (DES), was used in the United States from the 1940s to the 1970s to prevent miscarriage. Seven young women between the ages of 15 and 22 were seen at Massachusetts General Hospital with clear cell adenocarcinoma of the vagina between 1966 and 1969. This type of cancer had not previously been seen in patients younger than 30. A case–control study found an association with DES exposure during the first trimester (reviewed in Poskanzer and Herbst, 1977). In 1971, the Registry of Clear Cell Adenocarcinoma of the Genital Tract of Young Females was established to track affected offspring. The appearance of genital tract tumors peaked at age 19 and declined through age 22, with risk of clear cell adenocarcinoma of the vagina and cervix of 0.14 to 1.4 per 1000 exposed pregnancies (Herbst et al., 1977). Further, noncancerous alterations in the vagina, cervix, and uterus were estimated as high as 75% (Poskanzer and Herbst, 1977). Effects on the developing female reproductive tract may be due to effects on genetic pathways governing uterine differentiation (Huang et al., 2005). Male offspring were not spared the effects of DES, as epididymal cysts, hypotrophic testes, capsular induration, low ejaculated semen volume, and poor semen quality have been reported (Bibbo et al., 1977). The latent and devastating manifestations of prenatal DES exposure have broadened our concept of the scope of potential adverse outcomes of intrauterine exposures. Yet, recent studies suggest even farther-reaching effects; Newbold et al. (2006) reported that increased susceptibility to tumors and reproductive tract abnormalities from DES exposure may be passed on to future generations of exposed pregnant mice, and Al Jishi and Sergi (2017) discuss the evidence for transgenerational effects of DES in humans.

Tobacco Smoke

Tobacco smoke and its constituents may represent the leading cause of environmentally induced developmental disease and morbidity today (Rogers, 2008) (Fig. 10-1). Despite public health programs aimed at smoking cessation, approximately one-quarter of women smokers in the United States continue to smoke during pregnancy. A large body of epidemiology provides a well-characterized picture of the adverse consequences of developmental tobacco smoke exposure, including spontaneous abortion, perinatal death, sudden infant death syndrome (SIDS), disorders of learning, behavior and attention, and lower birth weight (Fried et al., 1998; Slotkin, 1998; Tuthill et al., 1999; Haug et al., 2000; Markussen Linnet et al., 2006; Rogers, 2008). Offspring of smoking mothers have a higher risk of obesity, hypertension, and type 2 diabetes than offspring of nonsmokers (Oken et al., 2008; Suzuki et al., 2009; Bakker and Jaddoe, 2011; Cupul-Uicab et al., 2012; Riedel et al., 2014).

Mitchell and Milerad (2006) reviewed the literature on smoking and SIDS and reported a relative risk of SIDS associated with maternal smoking of 2.86 (95% confidence interval 2.77 to 2.95) before prone-sleep-position intervention (i.e., putting infants on their backs for sleep reduces the overall risk of SIDS) and 3.93 (95% confidence interval 3.78 to 4.08) after intervention programs to reduce this nonsmoking cause. These authors estimated that about one-third of SIDS deaths might have been prevented had no fetuses been exposed in utero to maternal smoking.

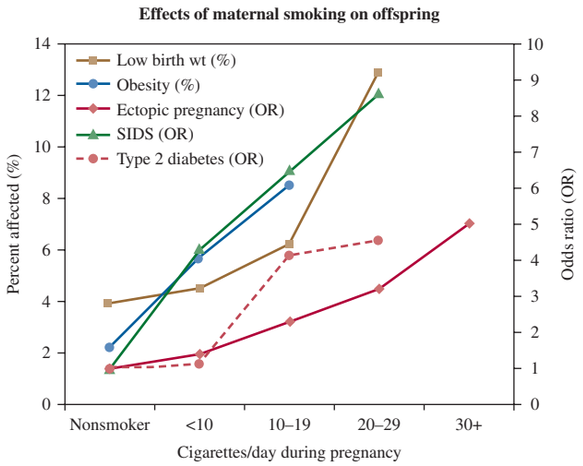

Figure 10-1. *Effects of maternal smoking on pregnancy and offspring.* These are effects for which dose–response relationships with maternal smoking have been established, but do not represent all of the effects of maternal smoking during pregnancy (see Rogers [2008]). (Plotted data are for preterm birth [spontaneous delivery at 33 to 36 weeks gestation] from Kyrklund-Blomberg and Cnattingius (1998); small for gestational age [SGA, less than 10th percentile for gestational week] from Windham et al. (2000); stillbirth from Wisborg et al. (2001); ectopic pregnancy from Handler et al. (1989); sudden infant death syndrome (SIDS) from Fleming and Blair (2007); offspring type 2 diabetes from Montgomery and Ekbom (2002); and offspring obesity [BMI > 97 percentile] from Von Kries et al., (2002).

Hackshaw et al. (2011) performed a review and meta-analysis of observational studies reporting odds ratios for nonchromosomal birth defects in offspring of women who smoked versus nonsmokers. There were 172 published articles comprising 173,687 malformed cases and 11.7 million controls. Significant associations with maternal smoking were found for these defects: cardiovascular, musculoskeletal, limb reduction, missing/extra digits, clubfoot, craniosynostosis, facial, eye, orofacial clefts, gastrointestinal, gastroschisis, anal atresia, hernia, and undescended testes. Lammer et al. (2005) found that maternal smoking was a risk factor for orofacial clefts, and that risk increased with genotypes indicating lack of enzymes involved in detoxification of smoke-derived chemicals. Gene–environment interactions may underlie the increased risk of other birth defects with maternal smoking (Shi et al., 2008). In a genome-wide association study, two genes, TBK1 on chromosome 12 and ZNF236 on chromosome 18, showed multiple single nucleotide polymorphisms associated with higher risk of nonsyndromic cleft palate in the presence of maternal smoking (Beaty et al., 2011). Perinatal exposure to tobacco smoke can also affect branching morphogenesis and maturation of the lung, leading to altered lung function (Gilliland et al., 2000; Pinkerton and Joad, 2000; Maritz and Harding, 2011). Nicotine, a primary component of tobacco smoke, is a known neuroteratogen in experimental animals and can by itself produce many of the adverse developmental effects of tobacco smoke, including impaired fertility, neurobehavioral effects, respiratory dysfunction, obesity, hypertension, and type 2 diabetes (Slotkin, 1998; Bruin et al., 2010).

The 2014 Surgeon General's report on the health consequences of smoking (U.S. DHHS, 2014) determined that there was sufficient evidence to infer a causal relationship between maternal smoking in early pregnancy and orofacial clefts, and between maternal smoking and ectopic pregnancy. In the same report, evidence was deemed suggestive but not sufficient to infer a causal relationship between maternal smoking and clubfoot, gastroschisis, atrial septal defects, spontaneous abortion, and disruptive behavioral disorders, particularly ADHD, in children.

Exposure to secondhand tobacco smoke (smoke from the lit end of cigarettes and that exhaled by smokers) also represents a significant risk to the pregnant nonsmoker and her baby, and such exposure has been associated with many of the effects caused by active maternal smoking (Windham et al., 2000; George et al., 2006; Mitchell and Milerad, 2006). Leonardi-Bee et al. (2008) found that, across many studies, exposure of nonsmoking pregnant women to secondhand smoke was associated with reduction of birthweight by 33 g or more, as well as a 22% increased risk of being of low birth weight (less than 2500 g). In another review and meta-analysis (Leonardi-Bee et al., 2011), nonsmoking pregnant women exposed to secondhand tobacco smoke had a 23% higher risk of stillbirth and a 13% higher risk of having a child with a congenital malformation.

Effects of maternal smoking on the epigenome of the developing offspring have been studied in multiple cohorts in Europe and the United States. Maternal smoking has been associated with changes in DNA methylation in cord blood and other offspring cells. DNA is methylated primarily at cytosines (to form 5-methyl cytosine) that are adjacent to a guanine in the DNA sequence (denoted as CpG). In 1062 cord blood samples from the Norwegian Mother and Child Cohort Study (MoBa), Joubert et al. (2012) discovered differential methylation for 26 CpGs (using Bonferroni correction) mapped to 10 genes. A high level of replication was achieved when a similar analysis was carried out on cord blood samples from the Newborn Epigenetics Study (NEST) cohort in Durham, North Carolina. The same 26 CpG methylation changes were found in both studies (Fig. 10-2). In a recent meta-analysis of results across 13 cohorts in the Pregnancy and Childhood Epigenetics (PACE) consortium, Joubert et al. (2016) found 568 CpG methylation changes (again, by using Bonferroni correction) between newborn blood of smoking versus nonsmoking mothers. The total number of significant CpG methylation changes was 6073 using a false discovery rate (FDR) correction of 5%. These CpGs included some genes related to normal and abnormal prenatal development as well as metabolism of xenobiotics. One of the genes most consistently affected by CpG methylation changes in these and other studies is the aryl-hydrocarbon receptor repressor (*AHRR*) gene that participates in AhR signaling involved in dioxin toxicity as well as cell growth and differentiation. This CpG in *AHRR* is currently considered a biomarker of smoking (Lee et al., 2017).

Retinoids

Excess vitamin A (retinol) has been known to be teratogenic in the rat for at least 60 years (Cohlan, 1954). Developing structures affected include the face, limbs, heart, central nervous system, and skeleton. Retinoic acid administration to the pregnant mouse (Kochhar, 1967) or hamster (Shenefelt, 1972) produces the same malformations. Understanding of the developmental effects of retinol, retinoic acid, and structurally related chemicals that bind to and activate specific nuclear receptors expanded rapidly in the 1990s (Chambon, 1994; Lohnes et al., 1994; Mendelsohn et al., 1994; Collins and Mao, 1999; Arafa et al., 2000). The teratogenic effects of vitamin A and retinoids have been reviewed (Nau et al., 1994; Collins and Mao, 1999).

A synthetic retinoid, 13-*cis*-retinoic acid (isotretinoin, Accutane), was marketed for the treatment of cystic acne beginning in 1982. Despite clear labeling of the drug at that time as FDA pregnancy category X (proven fetal risks clearly outweigh any benefit),

extensive physician and patient education, and strict requirements for prescription to women of childbearing potential, exposures of pregnant women still occurred. Infants with characteristic malformations involving the ears, heart, brain, and thymus were reported as early as 1983 (Rosa, 1983; Lammer et al., 1985). Dai et al. (1992) reported that among 115 exposed pregnancies not electively terminated, 18% ended in spontaneous abortion and 28% of live-born infants had at least one major malformation. Lammer (1992) found in another prospective study that there was nearly a doubling of the risk for premature delivery after first-trimester exposure, and about 50% of the exposed children had full-scale IQ scores below 85 at age 5. Almost 25% of women with an isotretinoin-exposed pregnancy did not recall having contraception counseling before starting their medication (Robertson et al, 2005). Rates of recommended birth control and monthly pregnancy testing were low. The Accutane brand was removed from the U.S. market in 2009, but generic isotretinoin continues to be marketed under other brand names worldwide. Adams (2010) has reviewed the neurobehavioral teratology of retinoids.

There has been concern about the use of topical retinoids during pregnancy. A recent meta-analysis ruled out a major increase in adverse pregnancy outcomes associated with use of topical retinoids, but the authors concluded that the statistical power of the analysis was inadequate to justify the use of topical retinoids during pregnancy (Kaplan et al., 2015).

Antiepileptic Drugs

Women of childbearing age that require treatment for epilepsy number over 1 million, while most current antiepileptic drugs (AEDs) have been shown to cause birth defects, cognitive impairment, and fetal death. As a class, AEDs including phenytoin, carbamazepine, and valproic acid are considered human teratogens. More recently, topiramate, used for the treatment of epilepsy as well as migraine and appetite suppression, has emerged as a teratogen strongly associated with oral clefts (Alsaad et al., 2015). Other AEDs including gabapentin, lamotrigine, oxcarbazone, levetiracetam, and zonizamide have now been used for over a decade, and studies to date suggest that these may be safer alternatives to the older AEDs or topiramate. The interested reader is directed to recent reviews (Tomson and Battino, 2005; Ornoy, 2006; Tatum, 2006; Hansen 2010; Voinescu and Pennell, 2015).

Phenytoin (diphenylhydantoin) has been used as an AED for over 70 years. Its antiepileptic effect works via inhibition of voltage-gated sodium channels. It is metabolized by the cytochrome P450 system to a reactive intermediate and then to an active metabolite. First described by Hanson and Smith (1975), the fetal hydantoin syndrome comprises craniofacial abnormalities, limb defects, growth deficiency, and mental retardation. This syndrome has been reported to occur in 5% to 10% of exposed offspring (Schardein, 2000). Putative mechanisms underlying the teratogenicity of phenytoin include folic acid deficiency and oxidative damage of tissue macromolecules (Hansen, 2010).

A report from the FDA (Rosa, 1991) linked carbamazepine use during pregnancy to neural tube defects. A later meta-analysis of 16 studies calculated a 2.89-fold increased risk of a major birth defect in offspring of pregnant women treated with carbamazepine (Matalon et al., 2002). Carbamazepine has been reported to be teratogenic in rats and mice (Schardein, 2000). An epoxide metabolite of carbamazepine was found to be teratogenic in mice in vivo (Bennett et al., 1996) but not in mouse or rat embryos cultured in vitro (Hansen et al., 1996). Thus, the teratogenicity observed in mice in vivo may have been related to maternal toxicity or to a different metabolite.

Elizabeth Robert (Robert and Guibaud, 1982) reported that of 146 cases of spina bifida aperta recorded in Lyon, France, 9 of the mothers had taken valproic acid (2-propylpentanoic acid) during the first trimester of pregnancy. The odds ratio in a case–control study was 20.6, and the estimated risk of a valproate-exposed woman having a child with spina bifida was 1.2%, similar to that for women with a previous child with a neural tube defect (CDC, 1982). The report was confirmed in other parts of the world (CDC, 1983). Several factors facilitated identification of valproate as a human teratogen, including an active birth defects registry, an

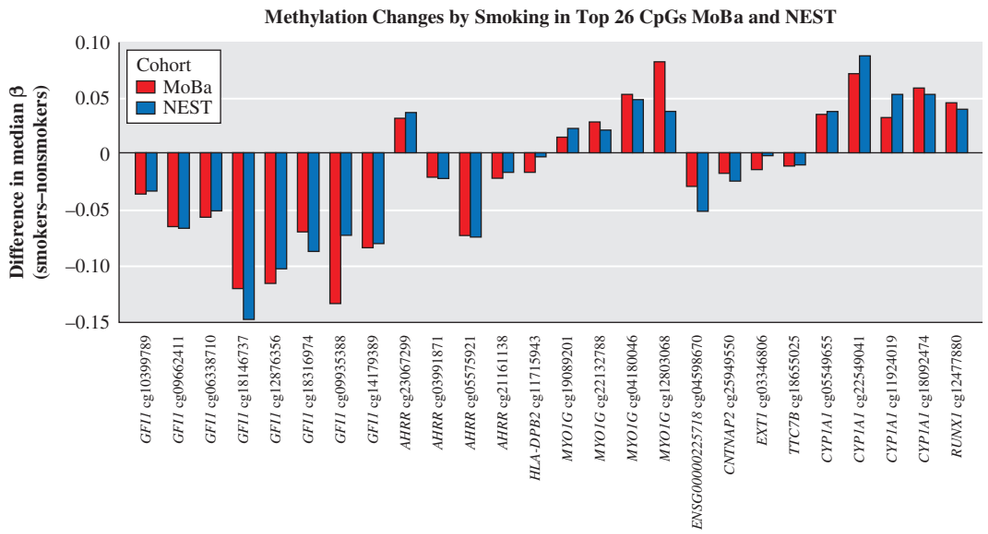

Figure 10-2. *Effects of maternal smoking on the epigenome of the newborn.* Association between maternal cotinine level and methylation of the top 26 affected CpGs (from 10 genes) in cord blood from the Norwegian mother and child (MoBa, red bars) study and the Newborn epigenetics study (NEST, blue bars). (From Joubert et al. [2012].)

interest by Robert in spina bifida, a question on anticonvulsant use in Robert's survey, and the prevalence of valproate monotherapy for epilepsy in the Lyon area (Lammer et al., 1987). Despite a great deal of research on the effects of valproate in multiple species, the mechanism of action remains elusive (Nau et al., 1991; Ehlers et al., 1992; Hauck and Nau, 1992). Use of inbred mouse strains differing in their sensitivity to valproate-induced teratogenesis has revealed several genes conferring sensitivity (Finnell et al., 1997, 2000; Bennett et al., 2000; Craig et al., 2000). Valproic acid is also a histone deacetylase inhibitor, and this may play a role in its teratogenicity (Eikel et al., 2006; Menegola et al., 2006). Similar to phenytoin, some studies have indicated a possible role of interference with folate metabolism (Hansen, 2010).

Epidemiology of Human Developmental Toxicity

Reproductive epidemiology is the study of associations between specific exposures of the father or pregnant woman and her conceptus and the outcome of pregnancy. In rare situations, such as rubella, thalidomide, isotretinoin, and Zika, where a relatively high risk exists and the outcome is a rare event, formal studies may not be needed to identify causes of abnormal birth outcomes, which are often detected by alert clinicians. The likelihood of linking a particular exposure with a series of case reports increases with the rarity of the defect, the rarity of the exposure in the population, a small source population, a short time span for study, and biological plausibility for the association (Khoury et al., 1991). In other situations, such as those with ethanol and valproic acid, associations are sought through either a case–control or a cohort approach. Both approaches require accurate ascertainment of abnormal outcomes and exposures, and a large enough effect and study population to detect an elevated risk. Therein lies one of the difficulties for epidemiologists studying abnormal reproductive outcomes. For example, it has been estimated that the monitoring of more than 1 million births would have been necessary to detect a statistically significant increase in the frequency of spina bifida following the introduction of valproic acid in the United States, where the frequency of exposure was less than 1 in 1000 pregnancies and the risk was only a doubling over the background incidence (Khoury and Holtzman, 1987). Another challenge to epidemiologists is the high percentage of human pregnancy wastage, perhaps as much as 31% in the peri-implantation period (Wilcox et al., 1988) and an additional 15% that are clinically recognized. Therefore, pregnancy failures related to a particular exposure may go undetected in the general population. Furthermore, with the availability of prenatal diagnostic procedures, some pregnancies with malformed embryos (particularly neural tube defects) are electively aborted. Thus, the incidence of abnormal outcomes at birth may not reflect the true rate of abnormalities, and the term prevalence, rather than incidence, is preferred when the denominator is the number of live births rather than total pregnancies.

Epidemiologic studies of abnormal reproductive outcomes are usually undertaken with three objectives in mind: the first is scientific research into the causes of abnormal birth outcomes and usually involves analysis of case reports or clusters; a second aim is prevention and is targeted at broader surveillance of trends by birth defect registries around the world, and the last objective is informing the public and providing assurance. In this regard, it is informative to consider the review by Schardein (1993) of the method and year by which human teratogens were detected. For 23 of 28 chemicals reviewed (including 9 cancer therapeutics, androgenic hormones, antithyroid drugs, aminoglycoside antibiotics, coumarin anticoagulants, DES, methylmercury, hydantoins, primidone, penicillamine, lithium, vitamin A, and retinoic acid), case reports presented the first evidence in humans. For two of these (DES and lithium), the case reports were soon followed by registries that provided confirmation, while for two others (methylmercury and hydantoins) follow-up epidemiology studies added support. For only four chemicals, alcohol, PCBs, carbamazepine, and cocaine, did an analytical epidemiological study provide the first human evidence. Evidence for one chemical, valproic acid, was first obtained by analysis of a birth defect registry. For the 28 chemicals in that review, human evidence of developmental toxicity preceded published animal evidence in 11 instances. Cohort studies, with their prospective exposure assessment and ability to monitor both adverse and beneficial outcomes, may be the most methodologically robust approach to identifying human developmental toxicants. The lack of cohort studies demonstrating risk for pregnancy may be in part due to the difficulty in making such associations, but may also reflect the fact that use in pregnancy is not associated with increased risk for the majority of drugs (Irl and Hasford, 2000).

Assessment of the developmental toxicity of tobacco smoke has benefitted greatly from the many epidemiological studies that have been carried out. Reasons for this success include the prevalence of smoking and secondhand smoke exposure (allowing large studies), good recall of exposure and biomarkers of exposure (e.g., the nicotine metabolite, cotinine), and comprehensive assessment of effects in offspring. The large number of studies has allowed powerful meta-analyses of the relationship between maternal smoking and birth defects (e.g., Hackshaw et al., 2011).

PRINCIPLES OF DEVELOPMENTAL TOXICOLOGY

James Wilson established principles of teratology in 1959 (Wilson, 1959) and updated them in his watershed monograph *Environment and Birth Defects* (Wilson, 1973) (Table 10-3). Despite significant advances in our knowledge of and approaches to the study of teratology, Wilson's principles have stood the test of time and remain basic to developmental toxicology. The following sections will cover these principles in some depth.

Table 10-3

Wilson's General Principles of Teratology

I. Susceptibility to teratogenesis depends on the genotype of the conceptus and the manner in which this interacts with adverse environmental factors.
II. Susceptibility to teratogenesis varies with the developmental stage at the time of exposure to an adverse influence.
III. Teratogenic agents act in specific ways (mechanisms) on developing cells and tissues to initiate sequences of abnormal developmental events (pathogenesis).
IV. The access of adverse influences to developing tissues depends on the nature of the influence (agent).
V. The four manifestations of deviant development are death, malformation, growth retardation, and functional deficit.
VI. Manifestations of deviant development increase in frequency and degree as dosage increases, from the no effect to the totally lethal level.

SOURCES: *From Wilson (1959, 1973).*

Critical Periods of Development and Susceptibility to Toxicity

Development is characterized by rapid changes in size, shape, biochemistry, physiology, and functionality. These changes are the consequence of sequential patterns of gene expression under the control of a cascade of epigenetic factors, the first of which are present in the egg prior to fertilization. These maternal factors are active in the zygote and very early embryo and then activate the embryonic genome, and sequential gene activation continues throughout development.

The embryo/fetus as a target for toxicity is continually changing as development proceeds. The concept that there are critical periods of sensitivity based on developmental stage at the time of insult is a somewhat unique consideration in developmental toxicology. While selected developmental stages are discussed here in the context of their known and potential susceptibility to toxicants, in reality development is a continuum. Comparative timing of developmental events in humans and some common laboratory species is presented in Table 10-4.

Gametogenesis is the process culminating in formation of the haploid germ cells or gametes, the egg, and sperm. Male and female gametes fuse during fertilization to form the diploid *zygote*, or one-celled embryo. The maternal and paternal genomes are not functionally equivalent in their contributions to the genome of the zygote, because the process of *imprinting* during gametogenesis confers on some genes a differential expressivity based on whether they are of maternal or paternal origin (Latham, 1999; Li and Sasaki, 2011). Imprinting involves cytosine methylation and changes in chromatin conformation, and may be susceptible to toxicants that affect these targets (Murphy and Jirtle, 2000). Both early nutrition (Waterland and Jirtle, 2003, 2004) and the estrogenic compound genistein (Dolinoy et al., 2006) have been shown to modify the methylation patterns of specific genes and cause altered phenotypes in mice. Anway et al. (2006) demonstrated a transgenerational effect of the fungicide vinclozolin in rats, in which male offspring (F1) of treated F0 females had reduced spermatogenic capacity which was transmitted to males in subsequent generations (F2 to F4) via an epigenetic mechanism. Transgenerational effects of environmental agents have been reviewed (Skinner, 2014).

Epigenetics refers to the biochemical changes that control chromatin conformation and gene expression. Epigenetic factors include DNA methylation, histone modifications, and expression of noncoding RNAs. While epigenetics provides the basis for imprinting of genes, the role of epigenetics is much broader (Rogers et al., 2010; Grace et al., 2011). Epigenetic marks may be erased and reestablished primarily during two periods of development during which broad scale demethylations of the genome are known to occur (Sasaki and Matsui, 2008). One is during migration and proliferation of the primordial germ cells (e.g., embryonic days 10.5 to 12.5 in the mouse). During this stage, imprinted genes are demethylated, followed by gender-specific remethylation during gametogenesis in offspring. The other period of widespread epigenetic reprogramming occurs after formation of the zygote and in the early embryo, with total genomic methylation being lowest at the early blastocyst stage (Hales et al., 2011). Epigenetic reprogramming represents a plausible target for environmental insults; examples of environmentally mediated epigenetic changes are emerging (Rogers et al., 2010; Perera and Herbstman, 2011; Skinner et al., 2011).

The *preimplantation* period comprises mainly an increase in cell number through a rapid series of cell divisions (*cleavage* of the zygote) with little growth in size. A stage termed the *blastocyst* follows, consisting of about a thousand cells surrounding a fluid-filled central cavity. The blastocyst may contain as few as three cells

Table 10-4

Timing of Key Developmental Events in Some Mammalian Species*

	RAT	RABBIT	MONKEY	HUMAN
Blastocyst formation	3–5	2.6–6	4–9	4–6
Implantation	5–6	6	9	6–7
Organogenesis	6–17	6–18	20–45	21–56
Primitive streak	9	6.5	18–20	16–18

Palate closure	16–17	19–20	45–47	56–58
Urethral groove closed in male	—	—	—	90
Length of gestation	21–22	31–34	166	267

**Developmental ages are days of gestation.*
SOURCE: Adapted from Shepard and Lemire (2004).

destined to give rise to the embryo proper (Markert and Petters, 1978), and these cells are within a region called the *inner cell mass.* The remainder of the blastocyst cells gives rise to membranes, trophoblast, and placenta. The fates of cells in the early embryo are not rigidly determined, and the preimplantation embryo has great restorative (regulative) growth potential (Snow and Tam, 1979). For example, Moore et al. (1968) demonstrated that individual cells from eight-celled rabbit embryos were each capable of producing normal offspring.

Toxicity during the preimplantation period is generally thought to result in either no or slight effect on growth (because of regulative growth recovery) or in death (through insurmountable damage or failure to implant). Preimplantation exposure to DDT, nicotine, or methyl-methane sulfonate results in body and/or brain weight deficits and embryo lethality, but not malformations (Fabro, 1973; Fabro et al., 1984). There are a few examples of preimplantation exposures leading to malformations. Exposure of mouse zygotes and blastocysts to the mutagens ethylene oxide (Generoso et al., 1987), ethylmethane sulfonate, ethylnitrosourea, or triethylene melamine (Generoso et al., 1988) for approximately 6 hours following fertilization resulted in malformed fetuses. Epigenetic changes were not examined, but given the developmental stages at the time of the exposure, this is a plausible target. Treatment of pregnant mice with methylnitrosourea on days 2.5, 3.5, and 4.5 of gestation resulted in neural tube defects and cleft palate (Takeuchi, 1984). Cyproterone acetate and medroxyprogesterone acetate are capable of producing malformations when administered on day 2 of gestation (Eibs et al., 1982).

Gastrulation is the process by which the trilaminar embryo is formed. *Ectoderm, mesoderm*, and *endoderm* are the resultant three germ layers. During gastrulation, cells migrate through a midline groove called the *primitive streak*, and this cell migration sets up morphogenetic fields in the embryo (Smith et al., 1994). Gastrulation is highly susceptible to teratogenesis. It is common for teratogens administered during gastrulation to produce anterior malformations, including those of the eye, brain, and face, indicative of damage to the anterior *neural plate*, one of the regions defined by the cellular migrations during gastrulation.

The formation of the neural plate in the midline ectoderm marks the onset of *organogenesis*, which as the name implies involves morphogenetic movements defining the rudiments of most structures of the body. This period extends from about the third to the eighth weeks of gestation in humans and is highly susceptible to teratogenesis. The embryo undergoes dramatic changes during this brief period, proceeding in the human from a few cell types in a trilaminar arrangement indistinguishable from most other vertebrate embryos, to a fetus clearly recognizable as human. The rapid changes during organogenesis require cell proliferation and migration, cell–cell interactions, and morphogenetic tissue remodeling. The *neural crest* cells originate at the border of the neural plate and migrate to form diverse structures throughout the embryo. Neural crest cells originating in the hindbrain migrate to form bone and connective tissues in the head (Krumlauf, 1993; Vaglia and Hall, 1999; Trainor and Krumlauf, 2001), while other neural crest cells form structures including melanocytes, enteric ganglia, adrenal medulla, and components of the cardiac outflow tract.

Within organogenesis, there are periods of peak susceptibility for each forming structure. The peak vulnerability to each malformation coincides with the timing of key developmental events in the affected structure. In general, morphogenesis proceeds from anterior to posterior in the embryo. The developmental fields for the brain and eyes are established early, and microphthalmia (small eyes) has an early critical period. Rudiments of the long bones of the limbs are established later, as is susceptibility to phocomelia (shortened limbs). There may be multiple windows of susceptibility to teratogenesis for a given structure, and the developing palate is a good illustration. The palate has multiple peaks of susceptibility during which cleft palate can be induced, one corresponding to the early establishment of the palatal folds and others corresponding to growth, elevation, and fusion of the palatal shelves. Cleft palate can be induced in mouse fetuses by maternal exposure to methanol as early as day 5 of gestation, with a peak sensitivity at day 7 and little or no sensitivity after day 9 (Rogers and Mole, 1997). In contrast, the typical peak critical period for induction of cleft palate in the mouse is between gestation days 11 and 13, during the stages of growth, elevation, and fusion of the palatal shelves. In NMRI mice, peak sensitivity to the induction of cleft palate occurred on day 11 for TCDD, day 12 for 2,4,5-trichlorophenoxyacetic acid, and day 13 for dexamethasone (Neubert et al., 1973). Detection of unexpected sensitive periods such as the one for induction of cleft palate by methanol may provide clues to the discovery of normal developmental processes. Using precisely timed administration of teratogenic dosages of retinoic acid to hamsters, Shenefelt (1972) elegantly demonstrated different gestational ages and durations of sensitive periods for induction of different malformations (Fig. 10-3).

The *fetal period,* from about day 57 to birth in humans, comprises tissue differentiation, growth, and maturation. Most organs are present and grossly recognizable, with further development during the fetal period aimed at attaining functionality prior to birth. Differentiation of the reproductive tract is one of the latest organogenetic events, with closure of the urethral groove in the male occurring at about 90 days of gestation. Toxic exposure during the fetal period is most likely to result in effects on growth and function. Functional deficits may not be apparent prenatally and may require postnatal observation and testing. Reviews of postnatal functional deficits of the central nervous system (Rodier et al., 1994; Miodovnik, 2011), immune system (Holladay and Luster, 1994; Dietert, 2008, 2014), and heart, lung, and kidneys (Lau and Kavlock, 1994) are available. Major structural alterations can occur during the fetal period, usually due to *deformations*, disruptions of previously normal structures. For example, extremities may be affected by amniotic bands, wrapping of the umbilical cord, or vascular disruptions, leading to loss of distal structures. One of the newer concepts in developmental toxicology is the idea of "developmental programming," in which the developmental environment influences the metabolic parameters of the offspring in a way that can affect life-long risk of disease (McMillen and Robinson, 2005; Gluckman et al., 2011; Barouki et al., 2012). Maternal nutrition has been the focus of much of this work, and there is a paucity of data concerning the long-term effects of developmental chemical exposure. Recently, Rogers et al. (2014) demonstrated that exposure of pregnant rats to diverse chemicals can result in increased blood pressure in offspring. Rats exposed prenatally to high dosages of ethanol have life spans shortened by about 20 weeks in females and 2.5 to 7 weeks in males (Abel et al., 1987).

Dose–Response Patterns and Thresholds for Induction of Developmental Toxicity

The relationships between growth retardation, malformations, and mortality in developmental toxicity studies are complex. These endpoints may represent a continuum of toxicity, with growth retardation, malformations, and then death occurring with increasing dosage. Malformations or death can occur without growth retardation, but this is atypical, and growth retardation and mortality often

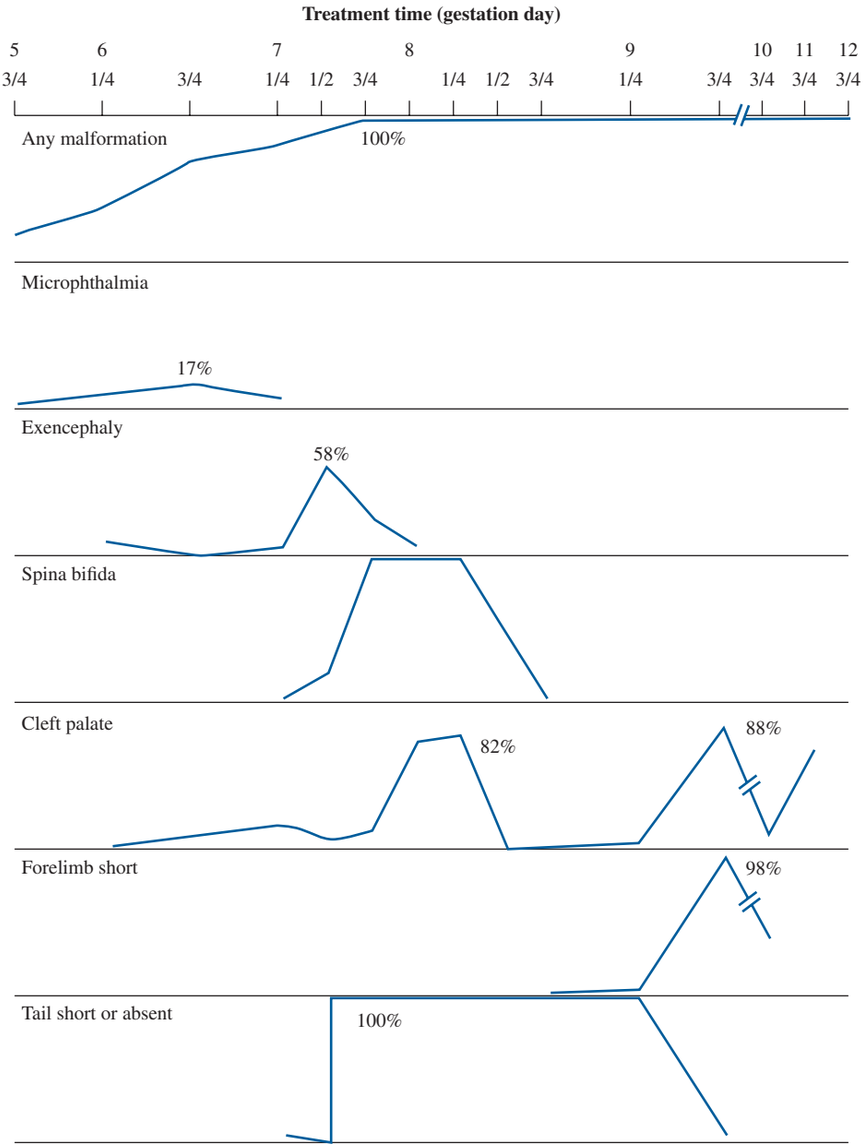

Figure 10-3. *Critical periods of sensitivity for induction of various defects by retinoic acid in the hamster.* Incidence of defects are estimates for the embryo/fetal LD_{50} maternal dosage. Note in the top panel that fewer malformations are induced on days 5 to 6, prior to organogenesis, indicating that, during this period, embryos for the most part either die or recover. Likelihood of malformation increases rapidly during gastrulation and reaches 100% during organogenesis. Peak incidence for each defect is enumerated and reflects timing of critical events in the development of each structure. (Redrawn from Shenefelt [1972].)

occur without malformations. Chemicals producing the latter pattern of response are considered embryotoxic or embryolethal but not teratogenic. Effects on functional endpoints in viable fetuses usually require postnatal assessment. Surviving birth is a rigorous test, and functional deficits may manifest as neonatal mortality.

The shape of the dose–response curve at low exposures is also important. The mammalian embryo possesses high restorative growth potential and cellular homeostatic mechanisms, which, along with maternal metabolic defenses, contribute to the conventional wisdom that mammalian developmental toxicity is a threshold phenomenon. In other words, it is assumed that there is a maternal dosage below which no increase in an adverse outcome will occur. Two experimental approaches to demonstrating a threshold were summarized by Daston (1993). One approach, exemplified by a large experiment with the herbicide 2,4,5-T (Nelson and Holson, 1978), suggests that no study is adequately powered to empirically evaluate the dose–response at very low effect levels—in this study, it was calculated that 805 litters per dose would be necessary to detect a 5% increase in resorption (early death) of embryos. The second approach is to demonstrate a threshold for the molecular mechanism underlying the observed effect. Few mechanisms of abnormal development have been thoroughly studied, but it is clear that embryonal repair capabilities and dose-dependent kinetics both support the plausibility of mechanistic thresholds. Lack of a threshold implies that exposure to any amount of a toxic chemical, even one molecule, can cause developmental toxicity. A point mutation in a critical gene could result from a single hit by a single molecule and, hypothetically, change or delete a critical gene product, leading

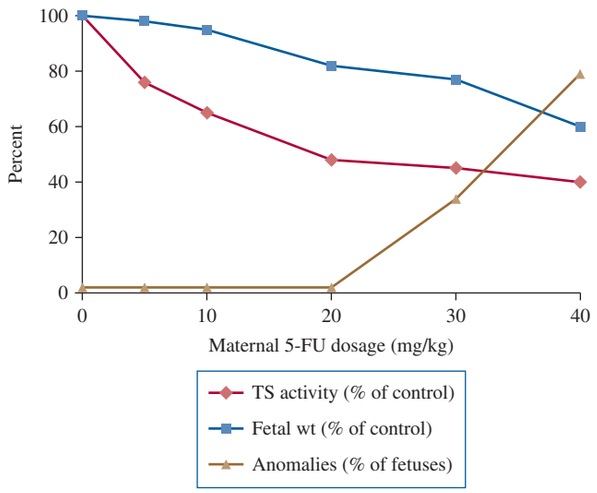

Figure 10-4. *Relationship between inhibition of embryonal thymidylate synthetase (TS) and adverse fetal outcome following maternal 5-fluorouracil (5-FU) administration on gestation day 14 in the rat.* 5-FU inhibits embryonal TS activity at dosages below 5 mg 5-FU/kg maternal body weight. Fetal weight is affected at ≥20 mg/kg and malformations increased significantly at ≥30 mg/kg. (Based on Shuey et al. [1994] and unpublished observations.)

to abnormal development. However, this would require that the molecule traverse the maternal system and the placenta and enter a critical cell in the embryo. Such an effect might be more likely at the zygote (one-cell) or the blastocyst stage (when only a few cells in the inner cell mass are embryo progenitors).

An apparent threshold for developmental toxicity based at least in part on cellular homeostatic mechanisms is suggested by studies on the teratogenicity of the cancer chemotherapeutic, 5-fluorouracil, in rats (Shuey et al., 1994). This chemical inhibits thymidylate synthetase (TS), thereby inhibiting DNA synthesis. TS inhibition is evident in the embryo at maternal dosages an order of magnitude lower than those required to produce malformations, and about fivefold below those affecting fetal growth (Fig. 10-4). The lack of developmental toxicity at dosages causing significant TS inhibition probably reflects the ability of the embryo to compensate for imbalances in cellular nucleotide pools.

For risk assessment, it is important to consider the distinction between individual and population thresholds. There is variability in sensitivity among humans, and the threshold for a population can be defined as the threshold for the most sensitive individual in the population (Gaylor et al., 1988). Although the biological target of a developmental toxicant may exhibit a threshold, background factors such as preexisting conditions or other exposures may leave individuals already at or even beyond the threshold for failure of that biological process. The concept of thresholds for reproductive toxicants has been reviewed by Piersma et al. (2011a).

MECHANISMS AND PATHOGENESIS

Mechanisms of teratogenesis include, but are not limited to, mutations, chromosomal breaks, altered mitosis, altered nucleic acid integrity or function, diminished supplies of precursors or substrates, decreased energy supplies, altered membrane characteristics, osmolar imbalance, and enzyme inhibition (Wilson, 1977). While not unique to development, such cellular insults may quickly trigger pathogenetic responses in the embryo. These pathogenetic events may include reduced cell proliferation, cell death, altered cell–cell interactions and signaling, reduced biosynthesis, inhibition of morphogenesis, or mechanical disruption of development.

A Case Study: The Teratogenicity of Cyclophosphamide

Experimentally elucidating mechanism(s) and pathogenesis of chemically induced teratogenicity can be daunting. The teratogenicity of the chemotherapeutic and immunosuppressive drug cyclophosphamide (CP) has been studied for over 50 years, and serves as a good example (Mirkes, 1985a; Ozolins, 2010). Because of its use for treating lupus, at least nine cases of human teratogenesis induced by exposure to CP during early pregnancy have been identified (Paladini et al., 2004). Experimental studies on the teratogenicity of CP illustrate approaches to understanding metabolic activation and elucidating teratogenic mechanisms and pathogenesis. Important to this work was the advent of mammalian whole embryo culture (WEC), wherein rodent or rabbit embryos are removed from the uterus at the beginning of organogenesis and grown in serum-containing media (New, 1978; Sadler and Warner, 1984; Ellis-Hutchings and Carney, 2010; Lee et al., 2012). Such embryos will grow normally in vitro for about 48 hours, completing much of organogenesis. WEC allows direct exposure, manipulation, and observation of embryos not possible in vivo; in contrast, it is devoid of maternal metabolism. Rodent WEC is also used as a screening system for developmental toxicity, which will be discussed later in the chapter.

Hepatic S9 fractions and cofactors were required for CP teratogenicity in WEC, demonstrating that it must be metabolically activated (Fantel et al., 1979; Sanyal et al. 1979). Activation was inhibited by metyrapone or carbon monoxide, indicating involvement of P450 monooxygenases. A stable derivative of the CP metabolite 4OHCP, 4-hydroperoxy-cyclophosphamide (4OOHCP), was tested in vivo (Hales, 1982) and in WEC (Mirkes, 1987). In WEC, the dysmorphology of the treated embryos was indistinguishable from that of embryos cultured with CP plus an activating system. Biotransformation of 4OHCP to phosphoramide mustard (PM) and acrolein (AC) occurs rapidly in vivo, and these metabolites, as well as 4-ketocyclophosphamide (4-ketoCP) and carboxyphosphamide (CaP), have all been studied for their teratogenicity. These experiments showed that 4OHCP was not teratogenic (Hales, 1983) and that the toxicity elicited by 4-ketoCP was unlike that of activated CP (Mirkes et al., 1981). Subsequent work on PM and AC demonstrated that the effects of PM on cultured rat embryos were the same as those of activated CP (Mirkes et al., 1981). In vivo, CP and AC administered to gestation day 13 rat embryos by intraamniotic injection caused hydrocephaly, open eyes, cleft palate, micrognathia, omphalocele, and tail and limb defects, while PM produced only tail and limb defects and hydrocephaly (Hales, 1982). These results strongly suggest that both PM and AC are teratogenic CP metabolites.

Experiments with tritiated CP revealed that 87% of bound radioactivity was in protein, 5% in DNA, and 8% in RNA (Mirkes, 1985b). CP and PM produced single-strand DNA breaks and DNA–DNA and DNA–protein cross-linking. To determine whether DNA cross-linking was required for teratogenicity, a monofunctional derivative of PM capable of producing single-strand breaks but not cross-links in DNA was tested; this derivative caused the same effects as PM (Mirkes et al., 1985). Subsequently, Little and Mirkes (1990) showed that 4-hydroperoxydechlorocyclophosphamide, a CP analog that breaks down to AC and a nonalkylating derivative of PM, did not damage DNA when embryos were exposed in WEC, but still retained its teratogenicity. They then showed that AC binds

to protein, whereas PM binds preferentially to DNA. Hales (1989) showed that PM and AC have distinctly different effects on limb buds growing in vitro. These results demonstrated different targets in the embryo for PM and AC, and that CP-induced DNA damage was caused by PM.

To illustrate pathogenesis, or how insults at the cell and molecular level translate to birth defects, consider cell cycle perturbations and cell death caused by CP. *Apoptosis* is a specific type of cell death under genetic control (Lavin and Watters, 1993); it is necessary for normal morphogenesis including sculpting the fingers and toes (Hernandez-Martinez and Covarrubias, 2011) and making appropriate functional connections between the central nervous system and distal structures. Cell proliferation is obviously a key facet of development—cells within the primitive streak of the gastrula-stage rat embryo have one of the shortest known cell cycle times of any mammalian cell, 3 to 3.5 hours (MacAuley et al., 1993). Cell proliferation rates vary spatially and temporally during development, as can be demonstrated by examining changes in the cell cycle distribution over time in different tissues during mid-to-late gestation (Fig. 10-5). Upsetting the balance between cell proliferation, cell differentiation, and apoptosis in the embryo via DNA damage may be key to the teratogenicity of CP.

CP caused an S-phase cell cycle block as well as widespread cell death in embryos of pregnant rats exposed on gestation day 10 (Fig. 10-6). Corroborating the S-phase cell cycle block, apoptosis was observed in areas of rapid cell proliferation (Chernoff et al., 1989; Francis et al., 1990). Similar embryonal cell cycle block and apoptosis were observed using activated CP in WEC (Little and Mirkes, 1992). The neuroepithelium of the embryo was sensitive to CP-induced apoptosis, while the heart was not. The neuroepithelium of the day 10 rat embryo has a cell cycle time of approximately 9.5 hours, compared to 13.4 hours in the heart. This difference is due to a longer G_0/G_1 phase in the heart cells compared to the neuroepithelium, and may contribute to the resistance of the heart to CP teratogenesis (Mirkes et al., 1989). Damage to DNA by PM occurs mainly during S-phase (Little and Mirkes, 1992), which is a relatively smaller proportion of the cell cycle in the heart than in the neuroepithelium.

Because bioactivation of CP is necessary for teratogenicity, Gomes-Carneiro et al. (2003) treated rats with an inhibitor of CYP2B1, the enzyme that activates CP, prior to CP injection. Severity and incidence of teratogenicity was reduced. Conversely, licorice extract, an upregulator of CYP2B1 expression, exacerbated the teratogenicity of CP (Park et al., 2011). Ginseng extract inhibits the CP detoxifying enzyme CYP3A, and coadministration enhanced CP teratogenicity. Thiol-containing molecules protect against alkylation, and the thiol molecules cysteine, glutathione, and Na-2-mercaptoethane sulfonate ameliorated CP teratogenicity (Ashby et al., 1976; Hales, 1981; Slott and Hales, 1986). Treatment with the antioxidant ascorbic acid attenuated CP-induced embryonic death and chromosomal damage (Kola et al., 1989), while another antioxidant, butylated hydroxyanisole, protected against CP teratogenicity in rats (Kang et al., 2003) and mice (Kim et al., 2003). Coadministration of L-carnitine or quercetin has also been shown to ameliorate the teratogenicity of CP, perhaps due to their antioxidant properties (Khaksary Mahabady et al., 2015, 2016).

The Molecular Basis of Dysmorphogenesis

Pathways of normal and abnormal development are being elucidated using molecular biology, genomics, proteomics, bioinformatics, tissue engineering, and computer modeling. Targeted gene disruption by homologous recombination (gene "knockout"), developed in the 1980s (Capecchi, 1989), has been used to study

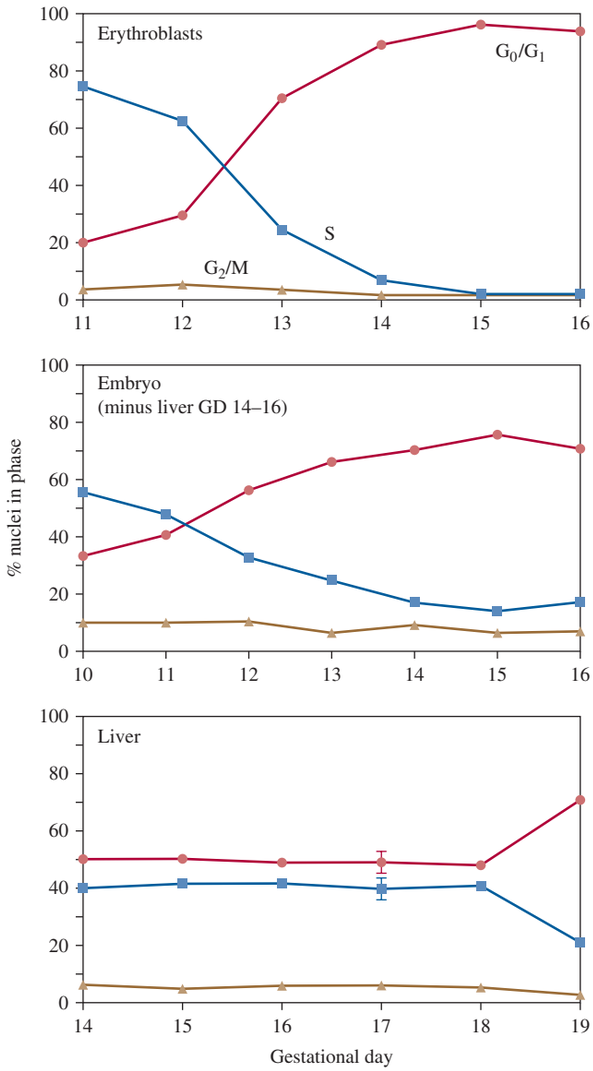

Figure 10-5. *Normal developmental changes in cell cycle distributions in erythroblasts, embryo (minus the liver after GD 13), and fetal liver. Percentages of cells in: ● G_0/G_1; ■ S; and ▲ G_2/M are shown for rat embryos between gestation days 10 and 19 (note changing x-axis range).* The proportion of cells in S-phase generally reflects proliferation rate, which decreases with developmental stage in the embryo and erythroblasts. The percentage of S-phase cells in the fetal liver remains fairly high and constant until near term, when a growth spurt occurs. (From Elstein et al. [1993].)

the loss-of-function of many gene products in developing and adult animals. An example is the retinoic acid receptor (RAR) family of nuclear ligand-inducible transcription factors that bind retinoid ligands, such as retinoic acid and 9-*cis* retinoic acid. Chambon and colleagues produced mice lacking RAR receptors either single or as combinations of knockouts. Single-receptor isoform mutants often exhibit normal development, suggesting that the receptors perform similar functions (i.e., there is functional redundancy), whereas double mutant neonates had widespread malformations of the skeleton and organs (Lohnes et al., 1994; Mendelsohn et al., 1994). The double RARγ–RARβ null mouse exhibits syndactyly, indicating that retinoic acid has a role in interdigital cell death (Dupe et al., 1999). The retinoid-X receptors (RXRα, β, and γ) bind 9-*cis* retinoic acid exclusively. RAR/RXR heterodimers form

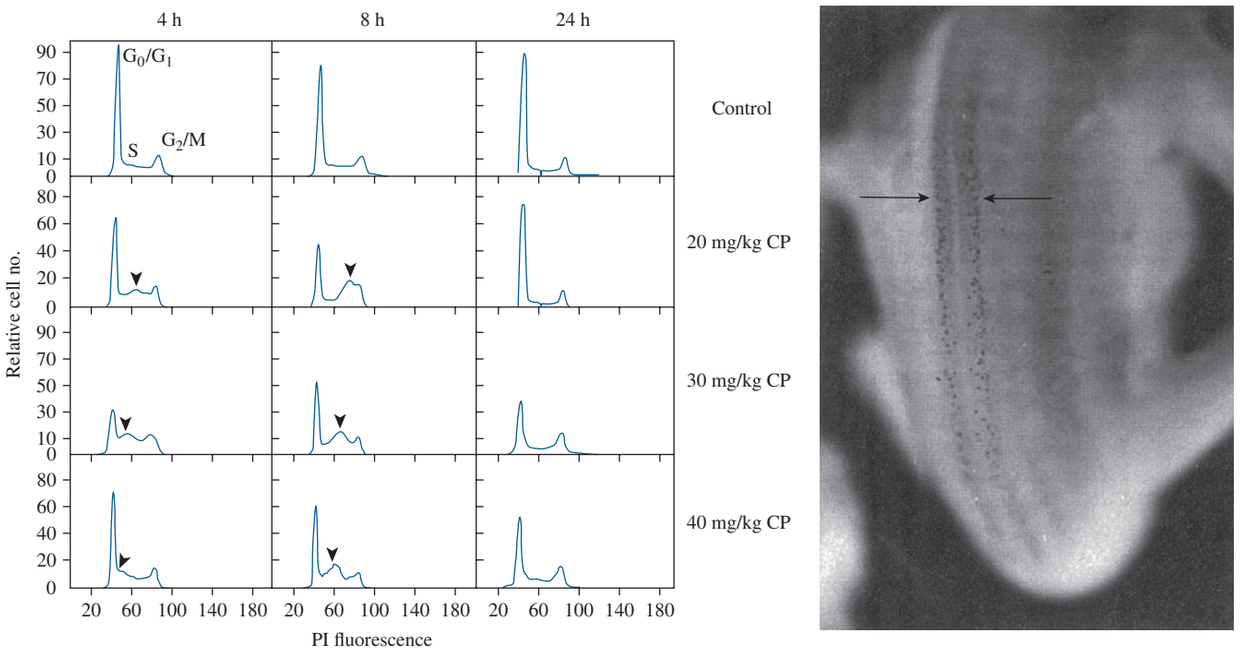

Figure 10-6. *Maternal cyclophosphamide (CP) administration on gestation day 10 in CD-1 mice produces perturbations of the embryonal cell cycle and cell death in areas of rapid proliferation. Left:* Cells are inhibited from progressing through the S (DNA synthetic) phase of the cell cycle, indicated by the abnormal population of cells (*arrowheads*) accumulating at progressively earlier stages of S-phase 4 and 8 hours after increasing maternal CP dosages. The upper panels show the normal GD 10 to 11 distributions, with the G_0/G_1, S, and G_2/M peaks identified in the upper left panel. By 24 hours postdosing, cell cycle distributions have returned to normal at 20 mg/kg, but remain abnormal at higher dosages. *Right:* Nile blue sulfate staining of a mouse embryo 24 hours after maternal CP dosing shows cell death (*stippling along either side of the midline, arrows*) in the neural tube, one of the most sensitive target sites for CP. (Adapted from Chernoff et al. [1989].)

and mediate retinoic acid signaling via transcriptional control in the embryo (Mark et al., 2006, 2009). Many spontaneous mutant and genetically engineered mouse strains are commercially available, and there is an expanding compendium of transgenic and mutants of other animals including zebrafish and frogs.

In addition to directly changing the DNA sequence using homologous recombination, it is also possible to modulate gene expression using synthetic oligonucleotides. Antisense oligonucleotides, with 15 to 25 nucleotides that are complementary to the mRNA to be disrupted (Hélène C and Toulmé JJ, 1990) can be synthesized. These probes can enter embryonal cells, and hybridization with cellular mRNA resulting in disruption of native message, such that gene function can be turned off at specific times. Using antisense oligonucleotides, Augustine et al. (1993) attenuated expression of the proto-oncogene Wnt-1 in mouse embryos developing in WEC. Exposure during neurulation produced mid- and hindbrain malformations similar to those seen in Wnt-1 null mice, as well as cardiac anomalies not observed in Wnt-1 knockouts created by homologous recombination. In mouse embryos in vitro, antisense attenuation of Wnt-3a caused anomalies of the forebrain, midbrain, and spinal cord. Simultaneously attenuating both Wnt-1 and Wnt-3a affected all brain regions and worsened the effect on the spinal cord, suggesting that these genes serve a complementary function in the development of the central nervous system. Morpholino antisense oligonucleotides contain nucleic acid analogs that resist degradation, and morpholinos have been used extensively in the study of zebrafish biology (Bedell et al., 2011). RNA interference is a more recent gene knockdown technique. Small interference (si) RNA and plasmid- and virus-encoded small RNAs can be used to downregulate the expression of specific genes posttranscriptionally (Shan, 2010). For techniques that modulate the level of mRNA, it is important to remember that selectivity and sensitivity are crucial to interpreting results of these studies. Off-target binding can occur, and appropriate controls of scrambled sequences or an unmodified vector are essential. Determining the level of mRNA change is critical because it is possible to decrease (knockdown) the level of mRNA without knocking it out. Additionally, the protein is usually the functional molecule, so it is essential to understand the relationship between changes in mRNA and protein when interpreting results. A transient decrease in mRNA may not change the level of functional protein.

Gain of gene function can also be studied by engineering genetic constructs with an appropriate promoter attached to the gene of interest. Ectopic gene expression can be ubiquitous or tissue-specific depending on the promoter selected to drive expression. Expression of the Hoxa-7 gene in mouse embryos using a chicken β-actin promoter resulted in multiple craniofacial and cervical vertebral malformations (Balling et al., 1989; Kessel et al., 1990). Transient overexpression of specific genes can be accomplished using adenoviral transduction. Hartig and Hunter (1998) injected an adenoviral vector containing either the bacterial beta-galactosidase or green fluorescent protein reporter gene under the control of the human cytomegalovirus early gene promoter into the intraamniotic space of neurulation-stage mouse embryos and achieved intense gene expression in the neuroepithelium.

Advances in gene targeting and transgenic strategies now allow modification of gene expression at specific points in development and in specific cell types. Conditional knockouts, knockdowns or knockins, inducible gene expression, and other techniques are being used to study in detail the effects of specific gene products on development (Mikkola and Orkin, 2005). Gene editing using the CRISPR-Cas9 system now allows targeting of specific sequences

in DNA for modification, and this technology has been applied to elucidating mechanisms of development. To come back to our example of retinoic acid and its receptors, Kumar et al. (2016) used CRISPR-Cas9 to produce mouse embryos with single and double nuclear receptor corepressor *Ncor1* and *Ncor2* mutants and demonstrated that *Ncor1;Ncor2* double mutants had small somites and cardiac distention similar to the phenotype of retinoic acid deficient embryos. Retinoic acid repression of *Fgf8* expression is required for different facets of morphogenesis, and this study demonstrated that NCOR1 and NCOR2 redundantly mediate the repression of *Fgf8* by retinoic acid. While much is understood about how retinoic acid turns on gene expression, little is known about mechanisms by which it represses gene expression.

Understanding the developmental consequences of altered gene expression requires understanding the temporal and spatial regulation of expression. Early studies of gene expression using in situ mRNA hybridization in tissue slices were supplanted by those using whole-mount techniques. In another approach, reporter transgenes containing a gene with a readily detectable product fused downstream of a selected regulatory region have been used to temporally map gene expression. The *Escherichia coli lacZ* (β-galactosidase) gene is commonly used for this purpose. The expression pattern of a gene can be localized by fusing the gene's upstream regulatory elements to *lacZ*, which will then be transcribed under control of those upstream elements (Zakany et al., 1990). Using these tools, it has been shown that retinoic acid (RA) can activate hox genes, and some hox genes have multiple RA response elements (RAREs). Evidence that RA-induced malformations in mouse embryos are related to changes in hox gene expression was first provided by staining of hox/*lacZ* transgenic embryos (Marshall et al., 1992). Within a few hours of RA treatment, *hoxb-1* expression extended anteriorly, suggesting that hox genes could be direct targets of RA induction. Regions of altered hox expression could be manifest as abnormal cell fate and morphogenesis (Marshall et al., 1996; Collins and Mao, 1999). Reporter genes have been used to study gene expression in zebrafish (Saydmohammed et al., 2011). In addition to mapping gene expression, cell lineage studies can be carried out by fusing *lacZ* to a constitutive regulatory sequence and introducing the construct into a somatic cell early in development. The reporter gene will then be expressed in and mark all progeny of the transfected cell. This method has been used to study postimplantation development in the mouse embryo (Sanes et al., 1986), although intracellular injection of fluorescent dyes has also proven to be reliable for cell lineage studies (Smith et al., 1994).

The use of modern biological techniques to elucidate a mechanism of chemical-induced developmental toxicity can be demonstrated by research on two perfluorinated alkyl acids (PFAAs), perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS). The PFAAs are a family of industrial chemicals that has been widely used as surfactants, hydrophobic and oleophobic treatments, and nonstick coatings. These chemicals are highly resistant to environmental degradation. Studies in experimental laboratory animals have demonstrated that developmental toxicity is among the most sensitive toxic effects produced by these chemicals (Lau et al., 2004). Exposure of pregnant mice to either PFOS or PFOA resulted in dose-related increases in offspring mortality during the first hours to days of life. While the toxic effects produced by PFOA and PFOS are similar, their mechanisms of action may be different. PFAAs have varied affinity for the peroxisome proliferator–activated receptor alpha (PPARα), and activation of PPARα is a putative mechanism of action for the developmental toxicity of PFAAs. To explore the role of PPARα activation in the developmental toxicity of PFOA and PFOS, Abbott and colleagues (Abbott et al., 2007, 2009; Wolf et al., 2008; Rosen et al., 2007, 2008, 2010) tested the developmental toxicity of these chemicals in PPARα null mice. Exposure of pregnant wild-type and PPARα knockout mice to PFOA revealed that neonatal mortality, the signature developmentally toxic effect of PFOA, was dependent on PPARα expression. Survival of PPARα null offspring was unaffected by maternal PFOA exposure, while survival of wild-type offspring was significantly reduced (Abbott et al., 2007). Surprisingly, when the same experiments were carried out with PFOS exposure, the PPARα null offspring were not protected against neonatal mortality (Abbott et al., 2009). Studies were undertaken to compare the ability of various PFAAs to activate mouse and human PPARα in COS-1 cells (a cell line derived from kidney cells of the African green monkey) transiently transfected with either a mouse or human PPARα-luciferase reporter gene construct, such that activation of the receptor caused light emission that could be quantified (Wolf et al., 2008). In agreement with the knockout mouse studies, PFOA activated both the mouse and human PPARα receptors at lower concentrations than did PFOS. Further evidence that PPARα activation was required for PFOA but not PFOS developmental toxicity came from studies of gene expression changes induced in fetal tissues by maternal treatment with PFOA or PFOS (Rosen et al., 2007, 2009). Although both PFOA and PFOS activated PPARα downstream genes, PFOA did so in a more robust fashion. This was also observed in liver tissue from adult mice treated with PFOA or PFOS. While PPARα knockout mice did not upregulate certain PPARα-related genes upon PFOA or PFOS treatment, the expression of other genes was changed by exposure to either of these PFAAs, indicating that the influence of either PFOA or PFOS may extend beyond activation of PPARα (Rosen et al., 2010). It remains to be determined which of the pathways downstream of PPARα are involved in the developmental toxicity of PFOA, and which non-PPARα-related pathways might be perturbed by PFOS.

MATERNAL ADAPTATIONS, METABOLISM, AND TOXICOKINETICS IN PREGNANCY

In determining the impact of chemical exposure on development, the route by which the mother is exposed, the timing of the exposure, and the extent to and from in which the chemical reaches the conceptus are important determinants of the impact on development. The maternal, placental, and embryonic compartments are distinct but interacting systems that undergo profound changes during the course of pregnancy.

Maternal Adaptations to Pregnancy

Maternal adaptations to pregnancy include changes in water and lipid content, hepatic metabolism, the gastrointestinal tract, cardiovascular system, excretory system, and the respiratory system (Hytten, 1984; Krauer, 1987; Mattison et al., 1991; Soma-Pillay et al., 2016) (Table 10-5). While these changes are necessary to maintain sufficient nutrition and eliminate waste products from the conceptus, they significantly impact the uptake, distribution, metabolism, and elimination of xenobiotics. For example, decreases in intestinal motility and increases in gastric emptying time result in longer retention of ingested chemicals in the upper gastrointestinal tract. Cardiac output in humans increases by 30% to 40% by the 27th week of pregnancy, while blood volume increases and plasma protein concentration and peripheral vascular resistance decrease. The relative increase in blood volume over red cell volume leads to borderline anemia and a generalized edema with about 70% elevation of extracellular space. Thus, the volume of distribution of a

SOURCES: From Hytten (1984), Krauer (1987), Mattison et al. (1991), and Soma-Pillay et al. (2016).

chemical and the amount bound by plasma proteins may change considerably during pregnancy. Renal blood flow and glomerular filtration rate also increase during pregnancy. Respiratory changes including increases in tidal volume, minute ventilation, and minute O_2 uptake can result in increased pulmonary distribution of gases and decreased time to reach alveolar steady state. Limited evidence suggests that maternal xenobiotic metabolizing enzyme activities also change during pregnancy (Juchau, 1981; Juchau and Faustman-Watts, 1983). Maternal hepatic P450 enzymes increase during pregnancy in humans; in contrast, during rat pregnancy hepatic monooxygenase activity decreases, probably due to decreased enzyme levels and competitive inhibition by circulating steroids (Neims et al., 1976). All of these maternal factors determine the amount of chemical and metabolites available to the embryo and are key to determining the extent of embryotoxicity. In one of the few studies of its type, Kimmel and Young (1983) found that a linear combination of the 45-minute and the 24-hour maternal blood concentrations was able to predict the litter response rate for pregnant rats dosed with 500 mg/kg sodium salicylate on gestation day 11. These kinetic parameters reflect the influence of peak and cumulative area under the drug concentration–time curve on the developmental toxicity of salicylate.

Role of the Placenta

The placenta is the interface between the mother and the conceptus. It plays a central role in transferring nutrients and waste products between the conceptus and mother. The placenta can mitigate embryonic xenobiotic exposure by helping to regulate blood flow, by offering a transport barrier, and by metabolizing chemicals (Slikker and Miller, 1994). Functionally, the placenta acts as a lipid membrane that permits bidirectional transfer of substances between maternal and fetal compartments. The extent of transfer depends on three major factors: the type of placentation, the physicochemical properties of the chemical, and rates of placental metabolism. Although there are marked species differences in types of placentas, orientation of blood vessels, and numbers of exchanging layers (Carney et al., 2004), these do not seem to play a dominant role in placental transfer of most chemicals.

It is important to note that virtually any substance present in the maternal plasma will cross the placenta to some extent. The passage of most drugs across the placenta seems to occur by simple passive diffusion. The rate of transfer from mother to conceptus is proportional to the diffusion constant of the drug, the concentration gradient between the maternal and embryonic plasma, the area of exchange, and the inverse of the membrane thickness (Nau, 1992). Important modifying factors to the rate and extent of transfer include lipid solubility, molecular weight, protein binding, the type of transfer (passive diffusion, facilitated, or active transport), the degree of ionization, and placental metabolism. Placental cells express mdr1a also known as P-glycoprotein (P-gp), an ATP binding cassette multidrug cellular efflux pump, and mice with a spontaneous mutation in the *Mdr1a* gene show a graded increase in susceptibility to avermectin Bla–induced cleft palate (Lankas et al., 1998). In the dosage range used in this study, homozygous mutants (*Mdr1a* –/–) were 100% susceptible to cleft palate, homozygous +/+ fetuses were totally resistant, and +/– heterozygous fetuses were of intermediate sensitivity. Weak acids appear to be rapidly transferred across the placenta during early pregnancy in rats and mice, due in part to the pH gradient between the maternal and embryonic plasma, which can trap ionized forms of the drug in the slightly more basic embryonic compartment (Nau and Scott, 1986). In humans and rabbits,

maternal serum pH is either similar to or slightly higher than the yolk sac fluid pH (Carney et al., 2004). Species differences in placental transport of immunoglobulins are an important consideration for safety assessment of biopharmaceuticals containing immunoglobulin Fc fragments, which are transported across the placenta by receptor-mediated endocytosis. The morphological path and timing of transport of immunoglobulins across the placenta vary among species. In humans and nonhuman primates, immunoglobulins are transported across the chorioallantoic placenta, and in rodents and rabbits across the inverted yolk sac. These large molecules are transported at the end of, or after, organogenesis in humans, nonhuman primates, and rabbits, while transport begins earlier in the developing rodent (DeSesso et al., 2012). Thus, the rodent could be a more conservative model for potential developmental toxicity of immunoglobulin-based biopharmaceuticals. Although smaller numbers limit the power of studies in nonhuman primates, the cynomolgus monkey is the most commonly used species for studies of the developmental toxicity of monoclonal antibody biopharmaceuticals (Pentsuk and van der Laan, 2009).

Maternal and Conceptus Xenobiotic Metabolism

The amount of xenobiotic, its form (parent or metabolite), and timing of delivery to the embryo are important components of understanding species differences in sensitivity (Nau, 1986). Despite the small size of the conceptus and the rapid rate of its development during organogenesis, there has been considerable progress in the area of embryonal toxicokinetics (Nau and Scott, 1987; Clark, 1993; Corley et al., 2003; Corley, 2010). Sensitive analytical methods can quantify metabolite formation and challenge the historical view, particularly for cytochrome P450–dependent monooxygenases, that the early embryo has low metabolic capabilities (Juchau et al., 1992). Using the WEC system, Juchau and co-workers demonstrated that the rat conceptus can bioactivate the proteratogen 2-acetylaminofluorene (2-AAF) to produce sufficient amounts of a toxic metabolite to induce dysmorphogenesis. Additionally, the proximate developmental toxicant, the 7-hydroxy metabolite, was different than the metabolite responsible for 2-AAF mutagenesis and carcinogenesis. These investigators later showed that embryos could further metabolize the 7-hydroxy metabolite to an even more toxic catechol. No previous induction was necessary for this activation step, demonstrating the presence of constitutive metabolizing enzymes in the embryo. Hines (2012) compiled findings on the ontogeny of hepatic drug metabolizing systems in humans, including significant prenatal expression for a number of enzyme classes. His survey suggested that metabolizing systems can be categorized into three classes based on the developmental trajectory of their expression (Table 10-6); Class I enzymes appear during the first trimester, remain elevated or decrease during gestation, and drop to low or no expression postnatally; Class II enzymes are expressed at a consistent level throughout gestation through adulthood; and Class III enzymes are nondetectable or low in the fetus, with expression increasing during 1 to 2 years postnatally and full expression not occurring until puberty for some Class III enzymes.

Physiologically Based Pharmacokinetic Models of Pregnancy

Physiologically based pharmacokinetic (PBPK) models provide the framework to integrate what is known about xenobiotic metabolism with physiology during pregnancy and embryo/fetal development into a quantitative description. Olanoff and Anderson (1980) described the kinetics of the antibiotic tetracycline in the pregnant rat and her litter in a model that incorporated fetal and placental growth. Gabrielson and co-workers (Gabrielson and Paalkow, 1983; Gabrielson and Larsson, 1990) were among the first investigators to develop PBPK models of pregnancy, and others have followed with an evolution of models (Fisher et al., 1989; O'Flaherty et al., 1992; Clark et al., 1993; Luecke et al., 1994, 1997; Young, 1998). The Fisher model included growth of several maternal tissues during pregnancy. The model of O'Flaherty and co-workers describes the entire period of gestation, and includes the uterus, mammary tissue, maternal fat, kidney, liver, other well-perfused maternal tissues, embryo/fetal tissues and yolk sac, and chorioallantoic placenta. This model includes changes in many compartments during pregnancy (including the embryo), as well as changes in blood flow and stage-dependent pH gradients between maternal and embryonic plasma. Transfer of xenobiotics across the placenta is diffusion-limited in this model. Luecke and co-workers developed quantitative models for human embryofetal growth for use in models of pregnancy (Luecke et al., 1994, 1997, 1999). For a review of chemical-specific PBPK models, see Corley et al. (2003) and Corley (2010).

A life-stage PBPK model was developed and integrated with adverse outcome pathways (AOPs) for developmental toxicity related to vasculogenesis, in vitro assays relevant to AOPs, and in vitro to in vivo extrapolation models as an approach to screening and prioritizing chemicals for potential risk (El-Masri et al., 2016). The PBPK model described chemical disposition during pregnancy, fetal, neonatal, infant, and adult stages to estimate a maternal

Table 10-6

Classification of Drug-Metabolizing Enzymes Based on Developmental Trajectories

CLASS I	CLASS II	CLASS III	
ADH1A	CYP2B6	ADH1B	GSTZ
CYP1A1	CYP2C19	ADH1C	FMO3
CYP3A7	CYP3A5	AOX	PON1
FMO1	EPHX1	CYP1A2	SULT2A1
GSTP	EPHX2	CYP2A6	UGT1A1
SULT1E1	GSTA	CYP2C8	UGT1A6
SULT1A3	SULT1A1	CYP2C9	UGT2B7
		CYP2D6	UGT2B15
		CYP2E1	CES1
		CYP3A4	CES2
		GSTM	

Class I enzymes appear during the first trimester, remain active during gestation, and have little or no postnatal expression; Class II enzymes are expressed at a consistent level during gestation through adulthood; Class III enzymes are low or absent in the fetus and increase during 1 to 2 years postnatally, some not being maximal until puberty. ADH, alcohol dehydrogenase; AOX, alternative oxidase; CES, carboxylesterase; CYP, cytochrome P450; EPHX, epoxide hydrolase; FMO, flavin monooxygenase; GST, glutathione S-transferase pi; GSTA, glutathione S-transferase alpha; GSTM, glutathione S-transferase Mu; GSTZ, glutathione S-transferase zeta; PON, paraoxonase; SULT, sulfotransferase; UGT, UDP glucuronosyl transferase.

SOURCE: Adapted from Hines (2012), with updates from R. Hines (personal communication).

exposure that would produce fetal blood concentrations similar to those producing toxicity in the in vitro assays. This estimate could be compared to maternal environmental exposure estimates to derive a margin of exposure.

RELATIONSHIPS BETWEEN MATERNAL AND DEVELOPMENTAL TOXICITY

All developmental toxicity ultimately results from insult to the conceptus at the cellular level, but in mammalian embryos the insult may occur through a direct effect on the embryo/fetus, indirectly through toxicity of the chemical to the mother or the placenta, or a combination of direct and indirect toxicity. Examples of maternal physiological conditions with the potential to adversely affect the conceptus include decreased uterine blood flow, anemia, under- or malnutrition, toxemia, altered organ function, autoimmune states, diabetes, electrolyte or acid–base disturbances, and elevated stress hormones (Chernoff et al., 1989; Daston, 1994). Chemical induction or exacerbation of such maternal conditions and the degree to which they contribute to abnormal development depend on maternal genetic background, age, parity, size, nutrition, disease, stress, and other health parameters and exposures (DeSesso, 1987; Chernoff et al., 1989; Rogers et al., 2005). These relationships are depicted in Fig. 10-7.

Distinguishing between direct and indirect developmental toxicity in standard developmental toxicity studies can be critical for interpreting results, as measurable maternal toxicity (e.g., decreased food or water intake, weight loss, clinical signs) is expected by design at the highest dosage level used. Such overt maternal toxicity can result from a number of underlying mechanisms, which are typically unknown. An understanding of the physiology underlying observed maternal toxicity is needed before one can begin to address the relevance of the observations for human risk assessment. Human developmental toxicants including ethanol and cocaine adversely affect the embryo/fetus predominately at maternally toxic exposures, and effects on the mother clearly contribute to their developmental toxicity. For example, the nutritional status of alcoholics is often poor and placental transfer of nutrients may be inhibited by ethanol. Chronic alcohol abuse alters maternal folate and zinc metabolism, which may play a role in the induction of fetal alcohol syndrome (Dreosti, 1993). Carney (2010) has constructed a useful decision tree for interpreting developmental toxicity observed concomitantly with maternal toxicity (Fig. 10-8).

Maternal Factors Affecting Development

Genetic Background The genetic makeup of the pregnant female has been well documented as a determinant of developmental outcome in both humans and animals. The incidence of cleft lip and/or palate (CL(P)), which in humans occurs more frequently in Caucasians than in African Americans, has been investigated in offspring of interracial couples in the United States (Khoury et al., 1983). Offspring of white mothers had a higher incidence of CL(P) than offspring of black mothers after correcting for paternal race, while offspring of white fathers did not have a higher incidence of CL(P) than offspring of black fathers after correcting for maternal race. Thus, maternal race (and presumable genotype) was the factor associated with differential risk.

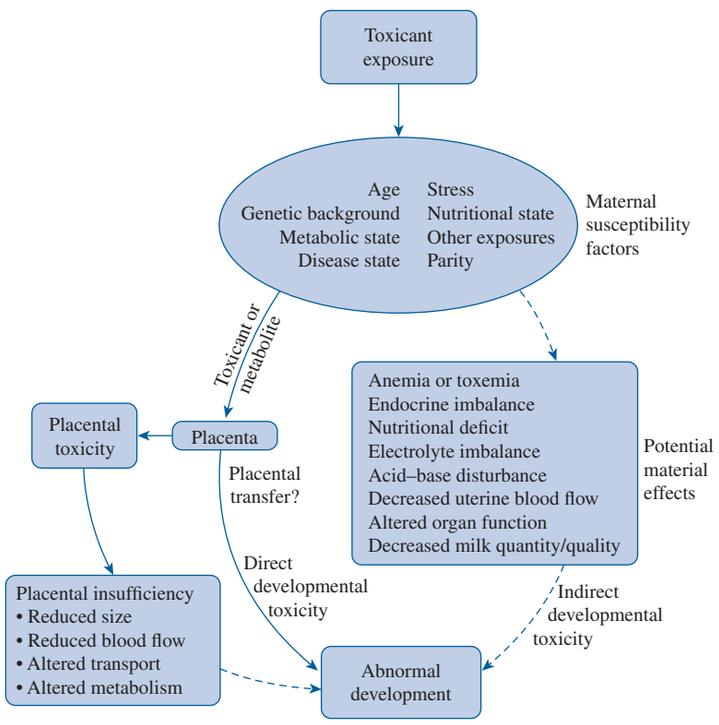

Figure 10-7. *Interrelationships between maternal susceptibility factors, metabolism, induction of maternal physiologic or functional alterations, placental transfer and toxicity, and developmental toxicity.* A developmental toxicant can cause abnormal development through any one or a combination of these pathways. Maternal susceptibility factors determine the predisposition of the mother to respond to a toxic insult, and the maternal effects listed can adversely affect the developing conceptus. Most chemicals traverse the placenta in some form, and the placenta can also be a target for toxicity. In most cases, developmental toxicity is probably mediated through a combination of these pathways.

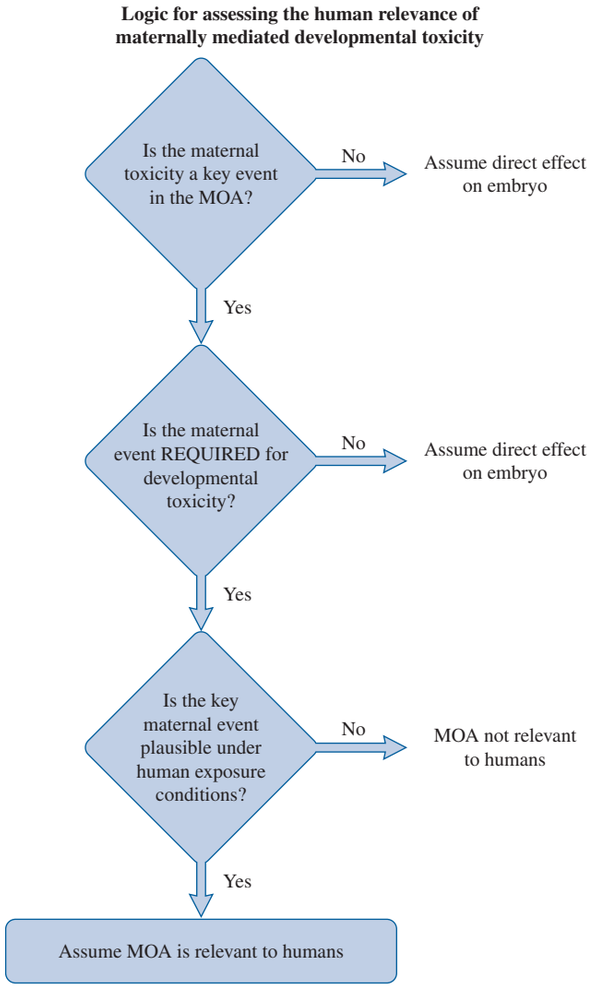

Figure 10-8. *Assessing the relevance to humans of a maternally mediated mode of action in rodents.* Flow chart for considering whether a maternally mediated mode of action (MOA) in animal studies is relevant to humans. When developmental toxicity is observed only at maternally toxic dosages, the MOA for developmental toxicity may be direct or indirect (secondary to the maternal toxicity). Maternally mediated developmental toxicity is relevant to humans if expected human exposure conditions could plausibly trigger that MOA. Knowledge of the MOA for developmental toxicity, which will likely require investigation beyond the dose–response study, is a prerequisite for using this approach. (Modified from Carney [2010].)

Two related mouse strains, A/J and CL/Fr, produced spontaneous CL(P) at 8% to 10% and 18% to 26% frequencies, respectively, and the incidence of the malformation depended on the genotype of the mother rather than that of the embryo (Juriloff and Fraser, 1980). The response of mouse embryos heterozygous for the curly-tail mutation to vitamin A also depends on the genotype of the mother (Seller et al., 1983). The teratogenicity of phenytoin has been compared in several inbred strains of mice, and again, it turned out that the susceptibility of offspring of crosses between susceptible A/J mice and resistant C57BL/6J (B6) mice was determined by the maternal, but not the embryonic genome (Hansen and Hodes, 1983).

Genes associated with susceptibility of mouse strains to valproic acid have been identified (Finnell et al., 1997; Bennett et al., 2000; Craig et al., 2000; Faiella et al., 2000; Okada et al., 2004, 2005). A study utilizing inbred B6 and DBA/2J (D2) mice to examine the role of maternal genotype in sensitivity to valproic acid (Downing et al., 2010) found that B6 mice were more susceptible to valproate-induced digital and vertebral malformations, while D2 mice were more susceptible to rib malformations. In a reciprocal cross between B6 and D2 mice, genetically identical F1 offspring responded in a manner consistent with maternal genotype: F1 offspring carried in a B6 mother had more vertebral and digital malformations while F1 carried in a D2 mother exhibited more rib malformations. It is possible that a maternal factor other than genotype was responsible for this finding.

Disease A number of maternal conditions and diseases can exert untoward effects during pregnancy. Chronic hypertension is a risk factor for the development of preeclampsia, eclampsia, and toxemia of pregnancy, and hypertension is a leading cause of pregnancy-associated maternal deaths. Uncontrolled maternal diabetes mellitus is a significant cause of prenatal morbidity. Certain maternal infections can adversely affect the conceptus (e.g., rubella virus, discussed earlier), either through indirect disease-related maternal alterations or direct transplacental infection. Cytomegalovirus infection is associated with fetal death, microcephaly, mental retardation, blindness, and deafness (MacDonald and Tobin, 1978), and maternal infection with *Toxoplasma gondii* is known to induce hydrocephaly and chorioretinitis in infants (Alford et al., 1974). The recent epidemic of microcephaly and other brain and eye defects in infants born to mothers infected during pregnancy with the Zika virus is the latest example of a maternal disease linked to birth defects (Rasmussen et al., 2016); in this case, the virus does appear to reach the brain of the fetus and to be directly toxic to neuroprogenitor cells (Faizan et al., 2016). A maternal factor common to many disease states is hyperthermia, which is a potent teratogen in experimental animals (Edwards, 1986), and there is a body of evidence associating maternal febrile illness during the first trimester of pregnancy with birth defects in humans, most notably neural tube defects, heart defects, and oral clefts (Warkany, 1986; Milunsky et al., 1992; Edwards 2006; Dreier et al., 2014; Shi et al., 2014).

Nutrition Dietary insufficiencies ranging from protein-calorie malnutrition to deficiencies of vitamins, trace elements, and/or enzyme cofactors are known to adversely affect pregnancy (Keen et al., 1993). Perhaps the most significant findings are from the landmark studies in which pregnant women at risk of having infants with neural tube defects (NTDs) were supplemented with folate (Wald, 1993; Czeizel, 2011). The largest and most convincing study was the Medical Research Council (MRC) Vitamin Study, in which supplementation with 4 mg of folic acid was associated with an over 70% reduction in recurrence of neural tube defects in previously affected mothers (MRC Vitamin Study Research Group, 1991; Bendich, 1993). The U.S. Centers for Disease Control and Prevention (CDC) recommended folate supplementation for women of childbearing age and folate supplementation of foodstuffs. In 1996, the U.S. FDA mandated enrichment of cereal grain products with folate. One study has demonstrated more than a doubling of mean serum folate concentrations across all sex and age groups since then (Dietrich et al., 2005). Yet, in the same population, less than 10% of women of childbearing age had the recommended erythrocyte folate concentration of more than 906 nmol/L shown to be associated with a reduction in NTD risk. The CDC (2004) estimated that the number of NTD-affected pregnancies in the United States declined from 4000 in 1995 to 1996 to 3000 in 1999-2000. While this survey indicates success of the folate fortification program, women capable of becoming pregnant were

urged to continue to follow the U.S. Public Health Service recommended consumption of 400 μg folate daily. Mills and Signore (2004) compared the rates of antenatal detection of NTDs in the United States (incomplete ascertainment and underprediction of NTDs) and Canada (more complete antenatal ascertainment) and determined that the studies that best identify cases of NTDs show that folic acid fortification is preventing around 50% of NTDs. Recent studies using multivitamins containing folate have achieved even better results (Czeizel et al., 2011). There is evidence that the effectiveness of folate in reducing neural tube defects may lie in its role in one carbon metabolism, particularly as a methyl donor for DNA methylation. In a mouse model of neural tube defects induced by methotrexate, a folate antimetabolite, total genomic DNA methylation was reduced in neural tube tissue of embryos with methotrexate-induced NTDs, and two genes in the Wnt pathway were especially affected (Wang et al., 2015).

Stress Diverse forms of maternal toxicity likely have in common the induction of a physiologic stress response, and understanding the effects of maternal stress on development may help interpret developmental toxicity observed in laboratory animals at maternally toxic dosages. Various forms of physical or psychological stress have been applied to pregnant animals in attempts to isolate the developmental effects of stress. Subjecting pregnant rats or mice to noise stress throughout gestation can produce developmental toxicity (Kimmel et al., 1976; Nawrot et al., 1980, 1981). Restraint stress produces increased fetal death in rats (Euker and Riegle, 1973) and cleft palate (Barlow et al., 1975), fused and supernumerary ribs, and encephaloceles in mice (Beyer and Chernoff, 1986).

Objective data on effects of stress during pregnancy in humans are difficult to obtain. Nevertheless, studies investigating maternal stress and pregnancy outcome have indicated a positive correlation between stress and adverse developmental effects including low birth weight and adverse mental health outcomes in offspring (Stott, 1973; Gorsuch and Key, 1974; Beydoun and Saftlas, 2008; Entringer et al., 2010; Dunkel Schetter and Tanner, 2012; Brunton, 2013).

Maternal and Placental Toxicity

The mother or the placenta may be the primary target for some developmental toxicants, with effects on the developing embryo/fetus occurring secondarily due to changes in the intrauterine environment or the nutrient/gas/waste exchange capabilities of the placenta.

Maternal Toxicity A retrospective analysis of relationships between maternal toxicity and specific types of prenatal effects claimed species-specific associations, yet, among rat, rabbit, and hamster studies, 22% failed to show any developmental toxicity in the presence of overt maternal toxicity (Khera, 1984, 1985). In a study designed to test the potential of maternal toxicity to affect development, Kavlock et al. (1985) administered 10 structurally unrelated compounds to pregnant mice at maternotoxic dosages. The only consistent developmental finding was an increased incidence of supernumerary ribs (ribs on the first lumbar vertebra), which occurred with 7 of the 10 compounds. Chernoff et al. (1990) dosed pregnant rats for 10 days with a series of compounds that had exhibited little or no developmental toxicity in previous studies. When these compounds were administered at maternally toxic dosages, diverse adverse developmental outcomes were noted including increased intrauterine death (two compounds), decreased fetal weight (two compounds), supernumerary ribs (two compounds), and enlarged renal pelves (two compounds). Two of the compounds produced no developmental toxicity despite substantial maternal toxicity. These diverse developmental responses led the authors to conclude that maternal toxicity characterized by weight loss or mortality was not consistently associated with any syndrome of developmental effects in the rat.

There have been a number of studies relating specific elements of maternal toxicity to developmental toxicity, including those in which the test chemical caused maternal effects that exacerbated the chemical's developmental toxicity, and instances in which developmental toxicity was thought to be secondary to maternal effects. However, clearly delineating the relative role(s) of indirect maternal and direct embryo/fetal toxicity is difficult. To follow are examples of studies in which this has been achieved to some extent.

Acetazolamide inhibits carbonic anhydrase and is teratogenic in mice (Hirsch and Scott, 1983). Although maternal weight loss was not correlated with malformation frequency, maternal hypercapnia potentiated the teratogenicity of acetazolamide. In C57Bl/6J mice, maternal hypercapnia alone resulted in right forelimb ectrodactyly, the characteristic malformation induced by acetazolamide. Correction of maternal acidosis failed to reduce developmental toxicity, suggesting that the primary teratogenic factor was elevated maternal plasma CO_2 tension (Weaver and Scott, 1984a, 1984b).

Diflunisal, an analgesic and anti-inflammatory drug, causes axial skeletal defects in rabbits. Developmentally toxic dosages resulted in severe maternal anemia (hematocrit = 20% to 24% vs. 37% in controls) and depletion of erythrocyte ATP (Clark et al., 1984). Teratogenicity, anemia, and ATP depletion were unique to the rabbit among the species studied. A single dose of diflunisal on day 5 of gestation produced maternal anemia that lasted through day 15. Concentration of the drug in the embryo was less than 5% of the peak maternal blood level, and diflunisal was cleared from maternal blood before day 9, the critical day for induction of similar axial skeletal defects by hypoxia. These results provide strong evidence that the teratogenicity of diflunisal seen in the rabbit was probably due to persistent hypoxia resulting from maternal anemia.

The anticonvulsant phenytoin can affect maternal folate metabolism in laboratory animals, which may play a role in its teratogenicity (Hansen and Billings, 1985). Heart rates were depressed by phenytoin in a dose-related manner in susceptible A/J mice but not in resistant C57Bl/6J mice (Watkinson and Millicovsky, 1983), and these authors proposed a mechanism of teratogenesis relating depressed maternal heart rate to embryonic hypoxia. Supporting studies have demonstrated that hyperoxia reduced the teratogenicity of phenytoin in mice (Millicovsky and Johnston, 1981).

Reduced uterine blood flow has been proposed as a mechanism of teratogenicity caused by hydroxyurea, which produces elevated systolic blood pressure, altered heart rate, decreased cardiac output, severely decreased uterine blood flow, and increased vascular resistance in pregnant rabbits (Millicovsky et al., 1981). Embryos exhibited craniofacial and pericardial hemorrhages immediately after treatment (Millicovsky and DeSesso, 1980a). The production of identical embryopathies by clamping the uterine vessels of pregnant rabbits for 10 minutes provided clear evidence of the role of reduced uterine blood flow in the teratogenicity of hydroxyurea (Millicovsky and DeSesso, 1980b).

Metallothionein (MT) synthesis can be induced by a variety of chemical and physical agents including metals, alcohols, urethane, endotoxin, alkylating agents, hyper- or hypothermia, and ionizing radiation (Daston, 1994). MT synthesis is also induced by endogenous mediators such as glucocorticoids and certain cytokines (Klaassen and Lehman-McKeeman, 1989). A mechanism common to the developmental toxicity of these diverse agents may

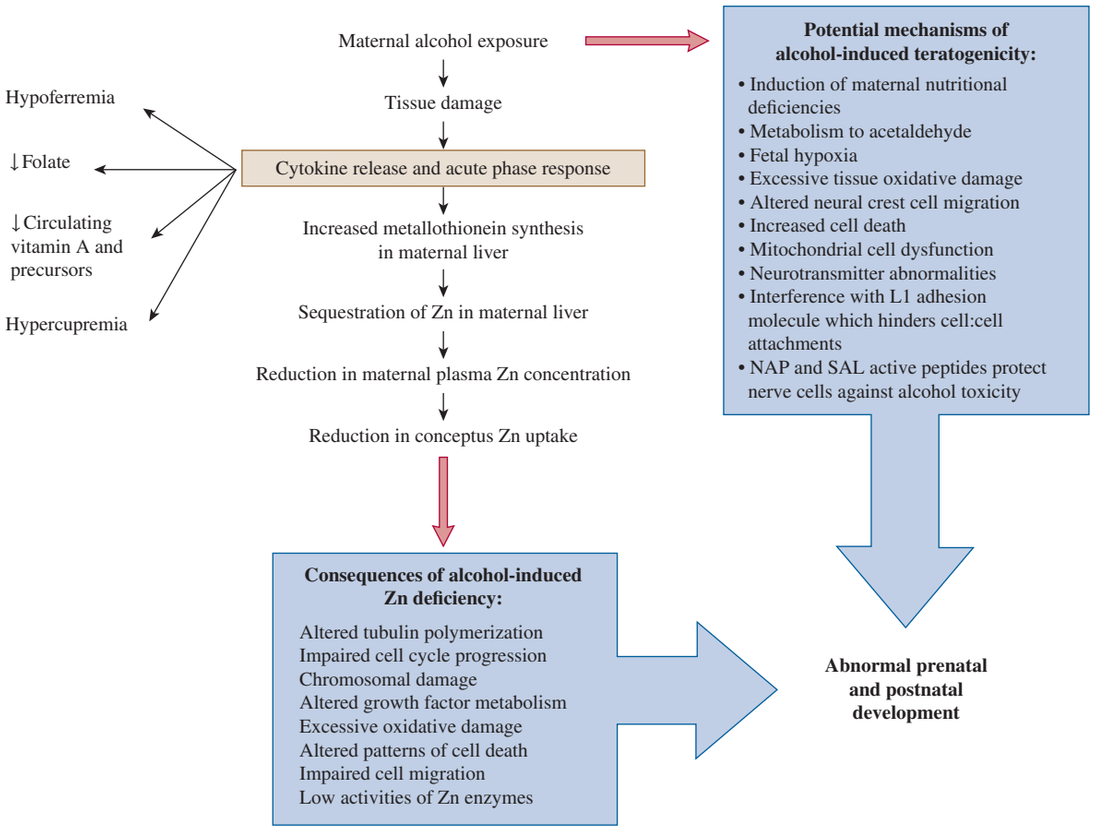

Figure 10-9. *Alcohol-induced acute phase response and sequence of events leading to conceptus zinc deficiency.* Multiple mechanisms underlie the teratogenicity of alcohol (box at upper right). Tissue damage in maternal tissues can initiate an acute phase response that includes induction of metallothionein in maternal liver, which removes available zinc from the maternal circulation, reducing availability to the conceptus. In addition to contributing to zinc deficiency in the embryo/fetus, an acute phase response can affect the metabolism of other essential nutrients, including folate, vitamin A, iron, and copper. NAP, neuroprotective octapeptide NAPVSIPQ; SAL, neurotropic nonapeptide SALLRSIPA. (Modified from Keen et al. [2010].)

be developmental Zn deficiency secondary to maternal MT induction. Induced synthesis can increase hepatic MT concentrations an order of magnitude above normal, leading to sequestration of circulating Zn in maternal liver, lower circulating Zn concentrations, and reduced Zn availability to the conceptus. Embryo/fetal Zn deficiency secondary to maternal hepatic MT induction has been demonstrated for diverse chemicals including valproic acid (Keen et al., 1989), 6-mercaptopurine (Amemiya et al., 1985, 1989), urethane (Daston et al., 1991), ethanol, and α-hederin (Taubeneck et al., 1994). Taubeneck et al. (1994) found a strong positive relationship between maternal hepatic MT induction and maternal hepatic ^{65}Zn retention, and a negative relationship between maternal MT induction and ^{65}Zn distribution to the fetuses. This is a clear example of a maternally mediated mechanism exacerbating or directly causing developmental toxicity, one that is applicable to diverse maternal insults and for which direct exposure of the conceptus to the causative agent is not necessary. Likewise, maternal ethanol exposure represents an excellent example of the interplay of indirect (maternally mediated) and direct developmentally toxic mechanisms (Fig. 10-9). Alcoholic mothers can exhibit blood alcohol levels that no doubt exert multiple direct effects on the embryo, including induction of cell death, altered neural crest cell migration, mitochondrial dysfunction, and effects on membrane integrity. At the same time, effects of chronic alcohol exposure on the mother include hepatic metallothionein induction and secondary embryofetal zinc deficiency, as described above. Additional maternal effects that may exacerbate teratogenicity include hypoferremia, reduced circulating folate, reduced circulating vitamin A, and hypercupremia. Genetic polymorphisms in both the mother and the fetus likely play roles in manifestation of fetal alcohol spectrum disorders as well, as evidenced by studies in humans and in animal models (Warren and Li, 2005). Despite literally thousands of epidemiological, clinical, and laboratory studies, the complex interplay of factors involved in the teratogenicity of ethanol is still being elucidated.

Placental Toxicity The placenta produces peptide and steroid hormones critical to the maintenance of pregnancy and the regulation of fetal and maternal metabolism, and can metabolize or store xenobiotics. Slikker and Miller (1994) listed 46 substances known to be toxic to the yolk sac or chorioallantoic placenta, including metals such as cadmium (Cd), arsenic, or mercury, cigarette smoke, ethanol, cocaine, endotoxin, and sodium salicylate. Cd is among the best studied of these, and it appears that the developmental toxicity of Cd during mid-to-late gestation involves both placental toxicity (necrosis, reduced blood flow) and inhibition of nutrient transport across the placenta. Maternal injection of Cd during late gestation resulted in fetal death within 10 hours in rats, concurrent with reduced uteroplacental blood flow, despite little cadmium entering the fetus (Parizek, 1964; Levin and Miller, 1980). The authors' conclusion that fetal death was caused by placental toxicity was supported by experiments in which fetuses were directly

injected with Cd. Despite fetal Cd burdens almost 10-fold higher than those following maternal administration, only a slight increase in fetal death was observed.

Cd is a transition metal similar in physicochemical properties to the essential metal zinc (Zn). Cd interferes with Zn transfer across the placenta (Ahokas et al., 1980; Sorell and Graziano, 1990), probably via metallothionein (MT), a metal-binding protein induced in the placenta by Cd. Because of its high affinity for Zn, MT may sequester Zn in the placenta, impeding transfer to the conceptus (induction of maternal hepatic MT by Cd or other agents can also induce fetal Zn deficiency, as discussed below). Cd inhibits Zn uptake by human placental microvesicles (Page et al., 1992), suggesting direct competition with Zn for membrane transport, and it may also competitively inhibit other Zn-dependent processes in the placenta. Coadministration of Zn ameliorates the developmental toxicity of Cd, indicating that interference of Cd with Zn metabolism is a key to its developmental toxicity (Ferm and Carpenter, 1967, 1968; Daston, 1982).

It has become evident that the placenta can undergo adaptive responses to the intrauterine milieu, and that such responses can influence the metabolic "programming" of the fetus (Myatt, 2006). Adverse conditions including hypoxia and nutritional deficiencies can lead to alterations in placental structure and function including altered expression or activity of transporters and receptors. Placental morphometry has been proposed as a biomarker of fetal programming (Thornburg et al., 2010). One role of the placenta that is key for fetal programming is as a regulator of glucocorticoid transfer between the mother and her fetus(es) (Seckl and Holmes, 2007). The enzyme 11β-hydroxysteroid dehydrogenase-2 (11β-HSD2) inactivates glucocorticoids; its activity in the placenta protects the fetus from overexposure to maternal stress hormone. In laboratory animals, lowering the activity of 11β-HSD2 by nutritional deficiency, gene ablation, or pharmacologic inhibitors leads to lower birth weight and causes increase in offspring adult blood pressure, circulating glucose concentrations, and hypothalamic-pituitary-adrenal axis activity.

DEVELOPMENTAL TOXICITY OF ENDOCRINE-DISRUPTING CHEMICALS

An "endocrine disruptor" has been broadly defined as "an exogenous agent that interferes with the production, release, transport, metabolism, binding, action, or elimination of natural hormones responsible for the maintenance of homeostasis and the regulation of developmental processes" (Kavlock et al., 1996). The Endocrine Society has stated: "an endocrine-disrupting substance is a compound, either natural or synthetic, which, through environmental or inappropriate developmental exposures, alters the hormonal and homeostatic systems that enable the organism to communicate with and respond to its environment" (Diamanti-Kandarakis et al., 2009). Given the critical role of hormones in directing differentiation of many tissues, the developing organism is particularly vulnerable to exposure to chemicals with hormonal (or antihormonal) activity. A wide variety of chemical classes (e.g., pesticides, herbicides, fungicides, plasticizers, surfactants, organometals, halogenated polyaromatic hydrocarbons, and phytoestrogens) have been shown to cause developmental toxicity by (1) acting as hormone receptor ligands; (2) altering hormone synthetic and metabolic enzymes; or (3) perturbing hypothalamic-pituitary release of tropic hormones. Interactions with the functions of estrogens, androgens, and thyroid hormones have been the most studied, but the underlying principles apply to other hormones as well.

Laboratory Animal Evidence

Chemicals with estrogenic activity induce pleiotropic effects, acting on diverse cell types with estrogen receptors, and can display cell- and organ-specific agonist and antagonist actions. The pattern of outcomes is generally similar across different estrogenic chemicals. Diethylstilbestrol (DES), discussed earlier, provides a well-characterized example of effects of a xenoestrogen on development, including malformations and functional alterations of the male and female reproductive tract and brain. In the CD1 mouse, effective dosages are 0.1 to 100 μg/kg on GD 9 to 16 (Newbold, 1995). At 10 to 100 μg/kg, total sterility of female offspring was noted, due in part to structural abnormalities of the oviduct, uterus, cervix, and vagina and to depletion of ovarian follicles. Male offspring show hypospadias while females exhibit excessive vaginal keratinization and vaginal tumors. Vaginal adenocarcinoma was seen at dosages as low as 2.5 μg/kg maternal body weight, and benign uterine tumors were seen at 0.1 μg/kg. In male offspring, sterility was observed at high doses, the result of retained rete testes and Müllerian duct remnants, abnormal sperm morphology and motility, cryptorchidism, abnormal reproductive tract secretions, and inflammation. DES exposure of pregnant mice also causes obesity in female offspring (Newbold et al., 2009). Other estrogenic (or antiestrogenic) developmental toxicants include estradiol (Biegel et al., 1998; Cook et al., 1998), ethinyl estradiol, antiestrogenic drugs such as tamoxifen and clomiphene citrate (Branham et al., 1988), and pesticides and industrial chemicals such as methoxychlor (Gray et al., 1989; Hall et al., 1997; Amstislavsky et al., 2003, 2004, 2006), *o,p*-DDT (Heinrichs et al., 1971), kepone (Gellert, 1978; Guzelian, 1982), dioxins (Mably et al., 1992; Gray et al., 1997a, 1997b), bisphenol A (Nagel et al., 1997; Peretz et al., 2014), and phytoestrogens such as genistein and coumestrol (Medlock et al., 1995; Rozman et al., 2006). Female offspring are generally more sensitive than males and altered pubertal development, reduced fertility, and reproductive tract anomalies are common findings.

Effects of developmental exposure to antiandrogenic chemicals are generally restricted to males, and include hypospadias, retained nipples, reduced testes and accessory sex gland weights, and decreased sperm production. Examples of chemical antiandrogens include pharmaceuticals such as the potent androgen receptor antagonist flutamide (Imperato-McGinley et al., 1992), the 5α-reductase inhibitor finasteride (Clark et al., 1990), the fungicide vinclozolin (Gray et al., 1994), and the DDT metabolite *p,p*-DDE (Kelce et al., 1995; You et al., 1998). Dibutylphthalate induces an antiandrogen phenotype in developing rats, but the effect does not appear to be due to direct interaction with the androgen receptor (Mylchreest et al., 1998, 1999). The critical developmental window for the effects of dibutylphthalate was gestation days 16 to 18 in the rat (Carruthers and Foster, 2005). Dietary exposure of pregnant rats to dibutylphthalate from gestation days 12 to 19 resulted in decreases in androgen responsive gene expression and testicular testosterone content in male fetuses and an antiandrogen phenotype in male offspring (Struve et al., 2009). A similar phenotype has been observed in offspring of dibutylphthalate-treated rabbits (Higuchi et al., 2003). Exposure of pregnant rats to mixtures of antiandrogenic chemicals have cumulative effects on development of male offspring (Rider et al., 2009, 2010; Hotchkiss et al., 2010; Hannas et al., 2011). Dose addition models appear to accurately predict the antiandrogenic effects of mixtures of phthalates (Howdeshell et al., 2015). The antiandrogenic effects of developmental exposure to phthalates (described above) has been labeled "the fetal phthalate syndrome" and Furr et al. (2014) have developed a short-term in vivo test, based on fetal testis testosterone production, that can

predict adverse effects on development of the male reproductive tract and other effects of phthalates.

Hypothyroidism during pregnancy and early postnatal development causes growth retardation, cognitive deficits, delayed eye opening, hyperactivity, and auditory defects in rodents. Polychlorinated biphenyls (PCBs) may act at several sites to lower thyroid hormone levels during development, and cause body weight and auditory deficits (Goldey et al., 1995; Goldey and Crofton, 1998). PCBs also cause learning deficits and altered locomotor activity in rodents (Eriksson et al., 1991; Schantz et al., 1995) and monkeys (Bowman, 1982; Schantz et al., 1991). The thyroid hormone synthesis inhibitor propylthiouracil (PTU) has been used to study the effects of chemically induced hypothyroidism on development of the brain (Gilbert, 2011). Addition of 1 to 3 ppm PTU to the drinking water of female rats during pregnancy and lactation produced deficits of thyroxine (T4) in the offspring, but only modest reductions in triiodothyronine (T3, the active thyroid hormone) at the high dose. Excitatory postsynaptic transmission was reduced and long-term potentiation was impaired in adult offspring despite the modest and transient effect on T3 during treatment.

Even mild thyroid deficiency during critical periods of development can have permanent adverse effects on brain development. Mild developmental thyroid insufficiency induces cortical heterotopia in rats (Goodman and Gilbert, 2007; Gilbert et al., 2014) and compromises activity-dependent neuroplasticity in the hippocampus of male rat offspring as adults (Gilbert et al., 2017).

Human Evidence

Despite the biological plausibility of effects demonstrated in numerous laboratory studies, the extent to which human health is being adversely impacted from exposures to environmental endocrine disruptors remains unclear. Reports in humans which are or may be relevant are of two types. The first type of reports are on observations of adverse effects on reproductive system development and function following exposure to chemicals with known endocrine activities that are present in medicines, contaminated food, or the workplace. These have tended to involve relatively high exposures to chemicals with known endocrine effects (e.g., DES). The second type of reports are related to epidemiologic evidence of increasing incidence of adverse reproductive and developmental outcomes having an endocrine basis. With the exception of DES, evidence is either insufficient to support a definitive link to an exposure or is variable across studies. Increasing trends have been reported for cryptorchidism (Toppari et al., 1996), hypospadias (Toppari et al., 1996; Paulozzi et al., 1997), semen quality (Carlsen et al., 1992; Skakkebaek and Keiding, 1994; Olsen et al., 1995; Auger et al., 1995; Bujan et al., 1996; de Mouzon et al., 1996; Fisch and Goluboff, 1996; Irvine et al., 1996; Vierula et al., 1996; Swann et al., 1997), and testicular cancer (Toppari et al., 1996). Recently, connections between environmental exposures and cryptorchidism and hypospadias (Toppari et al., 2010), and early onset of puberty in girls (Mouritsen et al., 2010) have been suggested. In a systematic review and meta-analysis of 185 studies across 40 years, 50 different countries, and 42,935 men, Levine et al. (2017) reported that sperm counts declined significantly between 1973 and 2011 in men from North America, Europe, Australia, and New Zealand.

Considerations of Endocrine Disruption in Screening and Testing

The findings of altered reproductive development following early-life exposures to endocrine disruptors prompted revisions of safety evaluation tests issued by the U.S. Environmental Protection Agency (EPA) (U.S. EPA, 1997). These include assessments of female estrous cyclicity, sperm parameters (total number, percent progressively motile, and sperm morphology in both the parental and F1 generations), the age at puberty in the F1 (vaginal opening in the female, preputial separation in the males); an expanded list of organs for pathology and/or histopathology to identify and characterize effects; as well as some triggered endpoints including anogenital distance in the F2 and primordial follicle counts in the parental and F1 generations. An important modification of prenatal developmental toxicity test guidelines aimed at improved detection of endocrine disruptors is the extension of the period of dosing to near the end of pregnancy in rodents in order to encompass the developmental period of urogenital tract differentiation.

REGULATORY ASSESSMENT OF RISK OF DEVELOPMENTAL TOXICITY

Experience with chemicals that have the potential to induce developmental toxicity in humans indicates that laboratory animal testing, surveillance of the human population (i.e., epidemiologic studies), and alert clinical awareness (Friedman, 2011) are all necessary to provide adequate public health protection. Laboratory animal investigations are guided both by regulatory requirements for drug or chemical marketing and by the need to understand mechanisms of toxicity.

Regulatory Guidelines for In Vivo Testing

Prior to the thalidomide tragedy, safety evaluations for reproductive effects were limited in the types of chemicals evaluated and the sophistication of the endpoints. After thalidomide, the FDA issued more extensive life-stage testing protocols (termed Segments I, II, and III) for application to a broader range of chemicals (U.S. FDA, 1966). These testing protocols, with minor variations, were adopted by regulatory agencies around the world and remained similar for nearly 30 years. Several factors including the historical experience of testing thousands of chemicals, increased knowledge of basic reproductive processes, the ever-rising cost of testing, the acknowledged redundancy and overlap of required protocols, a growing divergence in study design requirements of various countries, and the expanding international presence of the pharmaceutical and agrochemical industries succeeded in producing streamlined testing protocols that have been accepted internationally (U.S. FDA, 1994). These guidelines, the result of the International Conference of Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH), allow considerable flexibility in implementation depending on the particular circumstances of the chemical under evaluation. Key elements of the FDA Segment I, II, and III studies, the ICH protocols, the OECD equivalent of the FDA Segment II test, and the OECD-extended one-generation reproductive toxicity study (EOGRTS) are provided in Table 10-7. Details are available in the original publications and in several reviews (e.g., Manson, 1994; Claudio et al., 1999; Reuter et al., 2003; for the EOGRTS see OECD [2011], Moore et al. [2016], and Beekhuijzen et al. [2016a, 2016b]). Variations of these protocols include extensions of exposure to earlier or later time points in development and extensions of observations to postnatal ages with more sophisticated endpoints. For example, the EPA's Developmental Neurotoxicity Protocol for the rat includes exposure from gestation day 6 through postnatal day 10, and observation of postnatal growth, developmental landmarks of puberty (preputial separation, vaginal opening), motor activity, auditory startle, learning and memory, and neuropathology through postnatal day 60 (U.S. EPA, 1998).

Table 10-7

Summary of In Vivo Regulatory Protocol Guidelines for Evaluation of Developmental Toxicity

STUDY	EXPOSURE	ENDPOINTS COVERED	COMMENTS
Segment I: Fertility and general reproduction study	♂: 10 weeks prior to mating ♀: 2 weeks prior to mating	Gamete development, fertility, pre- and postimplantation viability, parturition, lactation	Assesses reproductive capabilities of ♂ and ♀ following exposure over one spermatogenic cycle or several estrous cycles
Segment II: Teratogenicity test	Implantation (or mating) through end of organogenesis (or term)	Viability and anatomy (external, visceral, skeletal) of fetuses prior to birth	Shorter exposure prevents metabolic adaptation and provides high exposure during gastrulation and organogenesis. Earlier dosing option for bioaccumulative agents. Later dosing to cover reproductive tract development
Segment III: Perinatal study	Last trimester of pregnancy through lactation	Postnatal survival, growth, and external morphology	To observe effects on development of major organ function during the perinatal period; may be more sensitive to adverse effects at this time
ICH 4.1.1: Fertility protocol	♂: 4 weeks prior to mating ♀: 2 weeks prior to mating	♂: Reproductive organ weights and histology, sperm counts, and motility ♀: Viability of conceptuses at mid-pregnancy or later	Improved assessment of ♂ reproductive endpoints; shorter treatment duration than Segment I
ICH 4.1.2: Prenatal and postnatal development, including maternal function	Implantation through end of lactation	Toxicity to pregnant vs. nonpregnant ♀; postnatal viability, growth, and function (behavior, maturation, reproduction)	Similar to Segment I study
ICH 4.1.3: Embryo/fetal development	Implantation through end of organogenesis	Viability and morphology (external, visceral, skeletal) of fetuses prior to birth	Similar to Segment II study. Usually conducted in two species (rodent and nonrodent)
OECD 414: Prenatal developmental	Implantation (or mating) through day prior to cesarean section	Viability and morphology (external, visceral, skeletal) of fetuses prior to birth	Similar to Segment II study. Usually conducted in two species (rodent and nonrodent)
OECD 443: Extended one-generation reproductive toxicity study	♂, ♀: 2 weeks or more prior to mating ♀: Through gestation and lactation ♂ Continue for 10 weeks	Clinical pathology and histopathology of parents and F_1; reproductive organ integrity, DNT, DIT on F_1 cohorts; triggers for F_2 production and testing	Preferred exposure route is dietary; replacement for two-generation study, using more endpoints and reducing animal use; technically challenging; flexible. See citations in text for details

DIT, developmental immunotoxicity tests; DNT, developmental neurotoxicity tests.

In 2006, the Regulation on Registration, Evaluation, Authorization and Restriction of Chemicals (REACH, 2006) was published. REACH requires that the toxicity of chemicals marketed or manufactured in the European Union above 1 metric ton per year must be characterized. The requirements are categorized by the annual tonnage of the chemical and are more extensive as the tonnage increases (Rovida et al., 2011). Requirements for reproductive and developmental toxicity are included for chemicals with an annual tonnage of 10 metric ton or more and are expected to require the largest use of live animals under REACH, which, although it encourages use of alternative toxicity tests to reduce animal use, does not currently deem screening tests for developmental toxicity sufficient to replace required whole animal tests (Scialli, 2008; Rovida et al., 2011). Alternatives to avoid animal testing may include read-across considerations of similar chemicals and the use of existing data from published studies (Scialli and Guikema, 2012), and the use of quantitative structure–activity relationship models (Wedebye et al., 2015).

In part because of the development of pharmaceuticals for use in children, the Workshop on Testing Strategies and Design of Juvenile Animal Studies was held in 2003 (Hurtt et al., 2004). Subsequently, the U.S. FDA and the European Medicines Agency (EMA) have promulgated guidelines for determining the need for and the design of nonclinical studies in support of registering such drugs (U.S. FDA, 2006; EMA, 2008). The design of such studies is flexible and would depend in part on the intended use of the drug (e.g., age range, duration of treatment, and drug target). To assess the value of such tests, juvenile animal data were compiled from over 200 studies and reviewed in a workshop (Bailey and Marien, 2011). The consensus was that the survey demonstrated the value of juvenile studies for the development of safe pediatric drugs.

The goal of standard regulatory studies is to identify a No Observed Adverse Effect Level (NOAEL), the highest dosage level that does not produce a significant increase in adverse effects in offspring or juvenile animals. NOAELs are then used in the risk assessment process along with uncertainty factors to assess the likelihood of effects in humans given certain exposure conditions, or to set allowable exposure limits. A preferable alternative, the benchmark dose approach, is discussed later in this chapter.

Multigeneration Tests

Information pertaining to developmental toxicity can also be obtained from studies in which animals are exposed to the test substance continuously over one or more generations (e.g., OECD Test Guideline 416 or U.S. EPA 870.3800). Piersma et al. (2011b) have questioned the value of including a second generation on overall outcome of the assessment. These investigators conducted a retrospective analysis of 498 rat multigenerational studies, and found that the second-generation mating and offspring rarely provided critical information. These authors instead recommended adopting a proposed OECD-extended one-generation test (Cooper, 2009; Vogel et al., 2010) for risk assessment. The extended one-generation test is flexible and could include a second generation if certain triggers were reached in the first generation. Others have argued that the triggers may be too sensitive and will too frequently result in invoking production of the second generation (Beekhuijzen et al., 2009). The extended one-generation reproductive toxicity study (EOGRTS) was adapted by the OECD as the OECD Test Guideline 433 (OECD, 2011).

Concordance of Data Between Laboratory Animals and Humans

There have been several reviews of the similarity of responses of laboratory mammals and humans to developmental toxicants. In general, these studies support the assumption that results from laboratory tests are predictive of potential human effects. Concordance is strongest when there are positive data from more than one test species. In a quantitative sense, the few comparisons that have been made suggest that humans tend to be more sensitive to developmental toxicants than is the most sensitive test species. While concordance among species for chemicals reported as positive is high, often special steps must be taken retrospectively to produce an animal model that reflects the outcome in humans (e.g., valproic acid) (Ehlers et al., 1992).

Frankos (1985) reviewed data for 38 compounds having demonstrated or suspect developmental toxicity in humans; all except tobramycin, which caused otologic defects, were positive in at least one test species and 76% were positive in more than one test species. Predictiveness was highest in the mouse (85%) and rat (80%), with lower rates for rabbits (60%) and hamsters (40%). Frankos identified 165 chemicals with no evidence of human effects; only 29% were negative in all species tested while 51% were negative in more than one species. Schardein and Keller (1989) examined concordance by species and developmental manifestation for 51 potential human developmental toxicants that had adequate animal data (3 human developmental toxicants did not). Thalidomide received the widest testing, with data from 19 species; 53% had data from 3 species, whereas 18% had data from 4 or 5 species. Across all chemicals, the most common findings in humans, rabbits, and monkeys were spontaneous abortion and fetal/neonatal death, followed by malformations and then growth retardation. In the rat, prenatal death, growth retardation, and then malformations was the typical pattern. All species showed at least one positive response for 64% of the human developmental toxicants and, with only one exception, all of the potential human developmental toxicants showed a positive response in at least one species. Overall, the match to the human, regardless of the nature of the developmental response, was rat, 98%; mouse, 91%; hamster, 85%; monkey, 82%; and rabbit, 77%. Jelovsek et al. (1989) reviewed the predictiveness of animal data for 84 negative human developmental toxicants, 33 with unknown activity, 26 considered suspicious, and 32 considered positive. Variables considered included the response of each species, the number of positive and negative species, percent positive and negative species, and mutagenicity and carcinogenicity. The compounds were correctly classified 63% to 91% of the time based on animal data, depending upon how the suspect and unknown human toxicants were considered. The various models had a sensitivity of 62% to 75%, a positive predictive value of 75% to 100%, and a negative predictive value of 64% to 91%. A summary comparison of rodent and rabbit results for 22 human developmental toxicants has been compiled by Daston and Knudsen (2010) (Table 10-8).

Table 10-8

Developmental Toxicity Findings in Rodents and Rabbits for Known Human Developmental Toxicants

CHEMICAL	RODENT	RABBIT	HUMAN
Cyclophosphamide	+	+	+
Diazepam	+		+
Diethylstilbestrol	+	+	+
Phenytoin/trimethadione	+	+	+
Ethanol	+		+
Lithium	+/−		+
Methylmercury	+		+
13-*cis*-Retinoic acid	+	+	+
Testosterone	+	+	+
Thalidomide	−	+	+
Valproic acid	+	+	+
Warfarin	+		+
Fumonisin B_1	+	−	+
Methimazole	+/−		+
Busulfan	+		+
Enalapril/captopril	+		+
Polychlorinated biphenyls	+/−		+
Cocaine	+/−		+
Misoprostol	+	−	+
Penicillamine	+		+
Tetracycline	−		+
Toluene	+		+

The + sign indicates developmental toxicity in that species; − indicates negative findings; +/− indicates an equivocal response. Blank spaces indicate chemical not tested in that species. The type of positive finding is not necessarily the same in all species.

SOURCE: Adapted from Daston and Knudsen (2010).

Children's Health and the Food Quality Protection Act

In 1993, the National Academy of Sciences published a report entitled "Pesticides in the Diets of Infants and Children," which brought to light the fact that infants and children differ both qualitatively and quantitatively from adults in their exposure to pesticide residues in food because of different dietary composition and intake patterns and different activities (NRC, 1993). This report, along with the report from the International Life Sciences Institute, entitled "Similarities and Differences Between Children and Adults" (Guzelian et al., 1992) provided background and impetus for passage of the Food Quality Protection Act (FQPA) of 1996. The FQPA incorporates an additional 10-fold safety factor for children, cumulative effects of toxicants acting through a common mode of action, aggregate exposure (i.e., same toxicant from different sources), and endocrine disruption. The inclusion (at the discretion of the EPA) of the 10-fold factor for calculating allowable intakes for children affects most strongly the pesticide industry, whose products can appear as residues in food. Children have different diets than adults and also have activity patterns that change their exposure profile compared to adults, such as crawling on the floor or ground, putting their hands and foreign objects in their mouths, and raising dust and dirt during play. Even the level of their activity (i.e., closer to the ground) can affect their exposure to some toxicants. In addition to exposure differences, children are growing and developing, which makes them more susceptible to some types of insults. Effects of early childhood exposure, including neurobehavioral effects, obesity, diabetes, cardiovascular disease, and cancer, may not be apparent until later in life (Hanson and Gluckman, 2014).

Alternative Testing Strategies

There has been a significant ongoing effort to identify and evaluate alternative test systems to refine, reduce, and replace whole animal regulatory tests for developmental toxicity (Brannen et al., 2016). Chernoff and Kavlock (1982) proposed a short-term rodent in vivo test. Other alternative assays use cultures of cells, developing organs/structures, and whole embryos in vitro, including those of worms, flies, frogs, fish, and mammals (Chapin et al., 2008; Piersma et al., 2010). Validation of alternative tests is a major issue (Neubert, 1989; Welsch, 1990). Initially, it was proposed that alternative models would be applicable to evaluating all chemicals, and would aid in the prioritization for standard mammalian testing. Despite continued progress, this is still a work in progress. Considering the complexity of embryogenesis and the multiple cellular and molecular mechanisms and target of potential teratogens, it may be unrealistic to expect a single test, or even a small battery of tests, to accurately predict the potential developmental activity of chemicals.

The In Vivo Chernoff–Kavlock Assay The in vivo test using rodents for prescreening chemical-induced developmental toxicity (Chernoff and Kavlock, 1982) streamlines the developmental toxicity assessment. Pregnant females are exposed to a limited number of test compound dosages during the period of major organogenesis. Dosages are selected to be near those inducing maternal toxicity. Assessment focuses on evaluating the offspring over a brief neonatal period for external malformations, growth, and viability. This test has proven reliable to identify developmental toxicants over a large number of chemical agents and classes (Hardin et al., 1987), and a regulatory testing guideline is available (U.S. EPA, 1985).

Rodent and Rabbit Whole Embryo Culture The rodent WEC continues to hold promise as an alternative model system (Augustine-Rauch et al., 2016), and has been extensively used as a tool for studies of chemical mechanism of action. For WEC, rodent or rabbit conceptuses are excised from the mother at an early stage of organogenesis with the embryo and yolk sacs intact (Fig. 10-10). Typically, conceptuses are cultured for up to 48 hours (Ellis-Hutchings and Carney, 2010), after which the embryos are scored for a number of growth and developmental parameters and assigned developmental scores (e.g., rodents: Brown and Fabro, 1981; Van Maele-Fabry et al., 1990; Zhang et al., 2013; rabbits: Carney et al., 2007). As a model for assessing developmental toxicity, WEC has the advantages of directly exposing mammalian embryos to the compound of interest and being able to distribute embryos in the same litter to different treatment groups. Disadvantages include the technically difficult and time-consuming process of excising the embryos and scoring them at the end of culture, and the cost in animals for obtaining the embryos and the rat serum used as culture medium. As an alternative or in addition to morphological scoring, effects of chemicals on gene expression in the embryos have been studied to discern common patterns ("signatures") of transcriptomic effects (Luijten et al., 2010; Robinson et al., 2010, 2011a, 2011b, 2012a, 2012b, 2012c, 2012d). There are key signaling pathways and intermediates in embryological development that hold promise as potential biomarkers of developmental toxicity (Robinson and Piersma, 2013).

Mouse Embryonic Stem Cell Tests Mouse embryonic stem cell tests (mESTs) examine effects of test chemicals on viability and differentiation of mouse embryonic stem cell lines. When the stem cells are placed into hanging drop culture, they aggregate and form "embryoid bodies." Cardiomyocyte differentiation in the cultures can be quantified by examining the cultures for beating cardiomyocytes. In a different mouse embryonic stem cell test, mouse embryonic stem cells are directly plated in an adherent model in 96 well plates and test chemical applied for up to 8 days (Barrier et al., 2011; Chandler et al., 2011) (Fig. 10-10). At the end of culture, cardiomyocyte differentiation is assessed by performing in-cell Westerns for cardiac myosin heavy chain and cell number is assessed using a fluorescent dye technique. Using this technique, the effects of the Phase I chemical library in the EPA's ToxCast program have been completed and a statistical model established for molecular mechanisms associated with altered differentiation reported (Chandler et al., 2011). Mouse embryonic stem cell tests have the advantage of using established cell lines, therefore not requiring live animals. They are also fairly rapid and inexpensive. One disadvantage is that these stem cell models evaluate embryonic cells during an early window of development and do not represent the full spectrum of cellular and molecular mechanisms and targets throughout embryogenesis. Human embryonic stem cell lines and induced pluripotent stem cells are also being developed for toxicity testing, with the obvious advantage of being human cells (Krtolica et al., 2009; Vojnits and Bremer, 2010; Ilic and Ogilvie, 2017). As for whole rodent embryo culture models above, significant progress has been made in identifying perturbations of gene networks in human embryonic stem cells that are predictive of developmental toxicity (Yamane et al., 2016). If key developmental nodes of gene expression networks can be confidently identified and occur in vitro, their predictive value may be very high.

The Zebrafish Submammalian species have been used for many years in the study of normal developmental biology, and among these animal models, the African clawed frog, *Xenopus laevis* or *X. tropicalis* (Bantle, 1995; Fort et al., 2000, 2004; Fort and Paul, 2002), and the zebrafish, *Danio rerio* (Love et al., 2004; Fraysse et al., 2006; Ton et al., 2006; Yang et al., 2009; Brannen et al.,

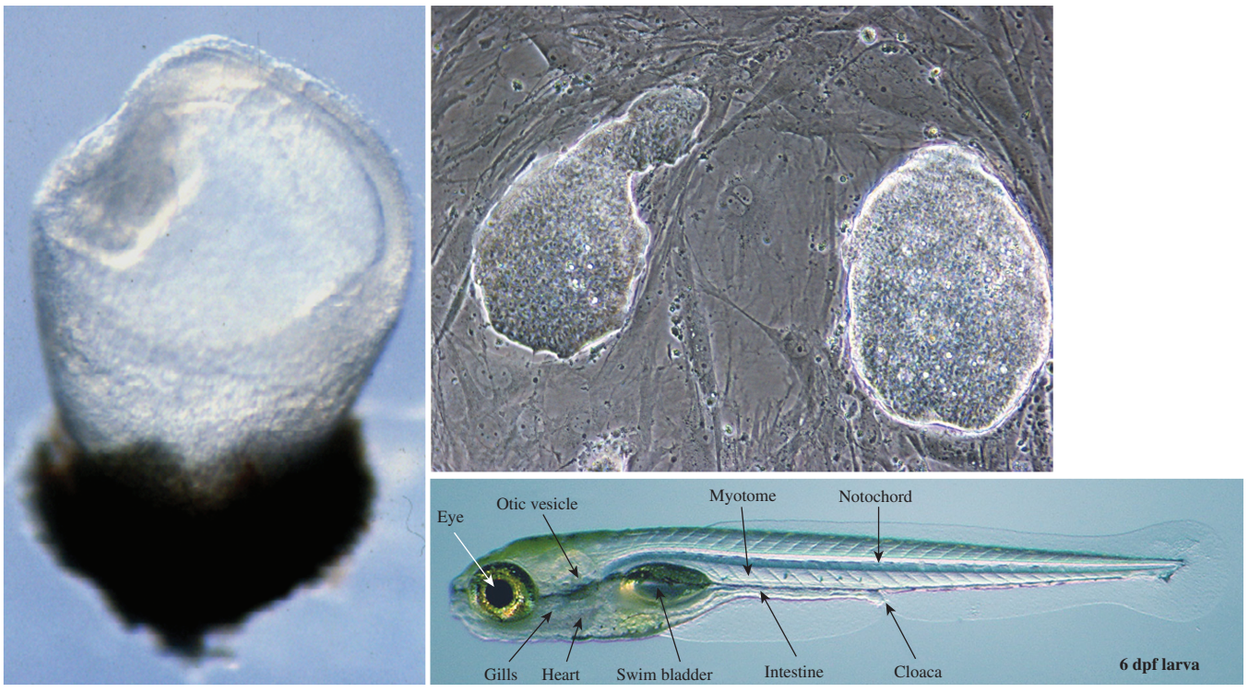

Figure 10-10. *Mouse whole embryo in culture, mouse embryonic stem cells, and zebrafish embryos are commonly used as screens for developmental toxicity. Left:* Mouse gestation day 8 embryo removed from the uterus with intact yolk sac and ectoplacental cone, ready to be cultured for up to 48 hours. (Picture courtesy of Dr E. Sidney Hunter.) *Top right:* Mouse embryonic stem cells (cell line J1) in pluripotent state maintained on a feeder layer of mitotically inactivated mouse embryonic fibroblasts. (Picture courtesy of Dr Kelly Chandler.) *Lower right:* Zebrafish larva at 6 days postfertilization (dpf). Note the transparency of the larva, facilitating observation of internal structures such as those labeled. (Zebrafish larva from Airhart et al. [2007], with permission.)

2010, 2013; McCollum et al., 2011; Sipes et al., 2011; Selderslaghs et al., 2012), have been used for developmental toxicology due to a number of advantages. Chief among the features of these species is rapid external development of the embryos, a large extant literature on their normal development, and the availability of genetic mutants and molecular biological tools for studying these embryos. In addition, they can be bred to produce large numbers of embryos in a relatively short period and are easy and inexpensive to maintain. In recent years, the zebrafish has emerged as the prominent submammalian species in use for developmental toxicity testing.

The zebrafish has gained increased usage in a number of research areas including developmental biology (e.g., Brannen et al., 2013; Truong et al., 2014; Planchart et al., 2016) and cancer research. These small fish exhibit a great deal of homology to higher vertebrates in their development, anatomy, physiology, and behavior. Their rapidly developing embryos are transparent, allowing visualization of internal anatomy (Fig. 10-10). Chemical toxicity studies in zebrafish have been comprehensively compiled and reviewed (McCollum et al., 2011). Zebrafish developmental toxicity testing can be carried out in 96-well plates, an approach used for assessment of the 309 chemical Phase I library in the EPA's ToxCast program (see below) (Padilla et al., 2012). For a review of zebrafish development and use of zebrafish as a disease model, see *Birth Defects Research Part C: Embryo Today: Reviews* 93(2), June 2011, an issue dedicated to this topic.

ToxCast The Toxicity Forecaster (ToxCast) program at the EPA Website https://www.epa.gov/chemical-research/toxicity-forecasting (Kavlock et al., 2012) includes hundreds of high-throughput assays directed at molecular and cellular targets of toxicity, a number of which are relevant to developmental toxicity. Sipes et al. (2011) evaluated statistical associations of ToxCast assay data with the mammalian developmental toxicity data in the EPA's Toxicity Reference Database, ToxRefDB. A high number of associations between the rat and rabbit in vivo data and the ToxCast data were discerned, and species-specific predictive models based on the ToxCast assays exhibited greater than 70% balanced accuracy.

Validation of Alternative Approaches to Testing for Developmental Toxicity Validation studies of the rat WEC test, the rat embryo limb bud micromass assay, and a mouse embryonic stem cell test have been carried out (Genschow et al., 2000, 2002, 2004; Brown, 2002; Piersma et al., 2004; Seiler et al., 2004; Spielmann et al., 2004). These studies involved interlaboratory evaluations of coded chemicals to assess the utility and reproducibility of assays. Analysis of the effects of chemical exposure included the development of "prediction models" which mathematically combine assay endpoints to determine which combinations and formulations are most predictive of mammalian in vivo results.

With continued development of in vitro platforms for developmental toxicity screening, the issue of proper validation of such assays is important. As discussed above, one approach is to develop lists of "positive" and "negative" reference chemicals and then test the ability of assays to properly categorize these. However, this approach does not consider how the concentrations of the chemicals in vitro compare to toxic blood or tissue concentrations in vivo. To address this gap, an approach that classifies chemical *exposures* (including concentrations) rather than chemicals per se as positive or negative has been proposed (Daston et al., 2010, 2014). This approach uses available data on toxic internal (e.g., blood or tissue) levels in vivo (human or test species) to characterize the chemical exposure as positive or negative, such that a given chemical can

be a positive at one concentration and a negative at a lower concentration. These exposure classifications can then be compared to effective concentrations in in vitro assays. A further approach combining generic physiologically based chemical kinetic models to predict in vivo target dose with in vitro toxic concentrations has been proposed for quantitative in vitro to in vivo extrapolation (Fragki et al., 2017).

Structure Activity and Read Across for Developmental Toxicity As we continue to increase our understanding of mechanisms of developmental toxicity, relationships between specific chemical structures or structural components and their effects on developing organisms are elucidated, increasing confidence in our ability to predict developmental toxicity based on chemical structure alone. This is, of course, the ultimate replacement for animal research, in that it requires only computational and bioinformatics tools. Approaches for quantitative structure–activity relationships have been developed over at least a couple of decades (Kavlock, 1990; Richard and Hunter 1996; Arena et al., 2004; Matthews et al., 2007a, 2007b; Wedebye et al., 2015). Read-across methods for predicting developmental toxicity of related chemicals can be employed using shared chemical structural components, or commonalities in their effects on the transcriptome. A good example of using shared structural components is the framework developed by Wu et al. (2013), based on known modes of action and empirical associations of chemical fragments in known developmental toxicants. This framework is a decision tree based on chemical structural features, which places chemicals into groups based on predicted receptor binding and chemical domains. The authors were able to categorize 716 developmental and reproductive toxicants into 25 categories using this expert system. A good example of classifying chemicals based on shared transcriptomal responses is the work of Rempel et al. (2015), who evaluated the effect of several histone deacetylase (HDAC) inhibitors and mercurials on the generation of neuroectoderm from human pluripotent stem cells. Their transcriptomic analysis correctly correlated gene expression with developmental toxicity among the HDAC inhibitors, and the expression of only eight genes was able to separate HDAC inhibitors from mercurials.

Contemporary and Emerging Elements of Developmental Toxicity Risk Assessment

As discussed below, there are a number of issues with using the No Adverse Effect Level (NOAEL) as the point of departure for risk assessments. Further, our present focus on apical outcomes such as malformations or lower fetal weight reveals little as to the initial target of the toxicant under study. The development of the benchmark-dose approach over the past 20 years or so has provided a clear improvement to the NOAEL, and approaches such as the development of biologically based dose–response models and adverse outcome pathways begin to piece together the early events in the etiology of abnormal development, in the hope that such knowledge will facilitate both more scientifically plausible risk assessments and relevant high-throughput assays based on key events leading to elucidated pathways.

The Benchmark Dose versus the No Observed Adverse Effect Level (NOAEL) The use of safety or uncertainty factors applied to an experimentally derived NOAEL to arrive at a presumed safe level of human exposure is predicated on the risk assessment assumption that a threshold for developmental toxicity exists (see the section "Principles of Developmental Toxicology"). A threshold should not be confused with the NOAEL, as the NOAEL is dependent entirely on the power and design of the study. Nor should the value obtained by the application of uncertainty factors to the NOAEL be confused with a threshold, as this exposure is only assumed to be without appreciable added risk.

The use of the NOAEL in the risk assessment process has been criticized for several reasons. Because it is dependent on statistical power to detect pair-wise differences between a treated and a control group, the use of larger sample sizes and more dose groups (which might better characterize the dose–response relationship) can only yield lower NOAELs, and thus better experimental designs are actually penalized by this approach. In addition, the NOAEL is limited to an experimental dose level, and an experiment might need to be repeated to develop a NOAEL for risk assessment. A final point relates to the fact that, given varying experimental designs and variability of control values, NOAELs actually represent different levels of risk in different studies.

Crump (1984) proposed using a mathematical model to estimate the lower confidence bounds on a predetermined level of risk (the "benchmark dose" [BMD]) as a means of avoiding many of the disadvantages of the NOAEL. The application of this approach to a large compilation of Segment II type data sets (Allen, et al., 1994a, 1994b; Faustman et al., 1994; Kavlock et al. 1995) demonstrated that a variety of mathematical models, including those that incorporate developmental-specific features such as litter size and intralitter correlations, can be readily applied to standard test results. On average, benchmark doses based on a 5% added risk of effect calculated on quantal endpoints (e.g., whether an implant was affected or not) were approximately equivalent to traditionally determined NOAELs. When the litter was used as the unit of response (did it contain at least one affected implant?), benchmarks calculated for a 10% added risk were most similar to the correspondingly determined NOAEL. Discrepancies between the benchmark dose and the NOAEL were most pronounced when one or more of the following conditions were present: a shallow dose–response, small sample sizes, wide spacing of experimental dosage levels, or more than the typical number of dose levels. These features tend to make determination of the NOAEL more problematic (usually higher) and the confidence limits around the maximum likelihood estimate broader (resulting in lower BMDs). Software, including the U.S. EPA's Benchmark Dose (BMDS) and Categorical Regression (CatReg), which determine whether data from separate studies can be combined into a single analysis, are available to the public at https://www.epa.gov/bmds.

Biologically Based Dose–Response Models and Adverse Outcome Pathways The introduction of statistical dose–response models for noncancer endpoints is the first step in developing quantitative, mechanistic models that will help reduce uncertainties in high-to-low dose and species-to-species extrapolation of experimental data. Biologically based dose–response models integrate pharmacokinetic information on target tissue dosimetry with molecular/biochemical responses, cellular/tissue responses, and developmental toxicity (O'Flaherty, 1997; Lau and Setzer, 2000; Lau et al., 2001; Setzer et al., 2001). Gaylor and Razzaghi (1992) proposed a model that related induction of cleft palate to fetal growth inhibition, and Gaylor and Chen (1993) proposed a model relating fetal weight and the probability of fetal abnormality. Shuey et al. (1994) presented a model using the cancer chemotherapeutic 5-fluorouracil. These investigators postulated that the developmental toxicity observed in the term fetus was due to an active metabolite (FdUMP) inhibiting the enzyme thymidylate synthetase, causing depletion of thymidine, decreased DNA synthetic rates,

reduced cell proliferation, and ultimately, reduced tissue growth and differentiation. Each step in the pathogenesis was quantified experimentally and the relationships were described by Hill equations. The individual equations were then linked in an integrated model to describe the entire relationship between administered dose and the incidence of hind limb defects (Fig. 10-11). While this is still an empirically based model, the process clearly demonstrated the utility of the approach in understanding the relative importance of various pathways of abnormal development and in providing a basis for models that incorporate species-specific response

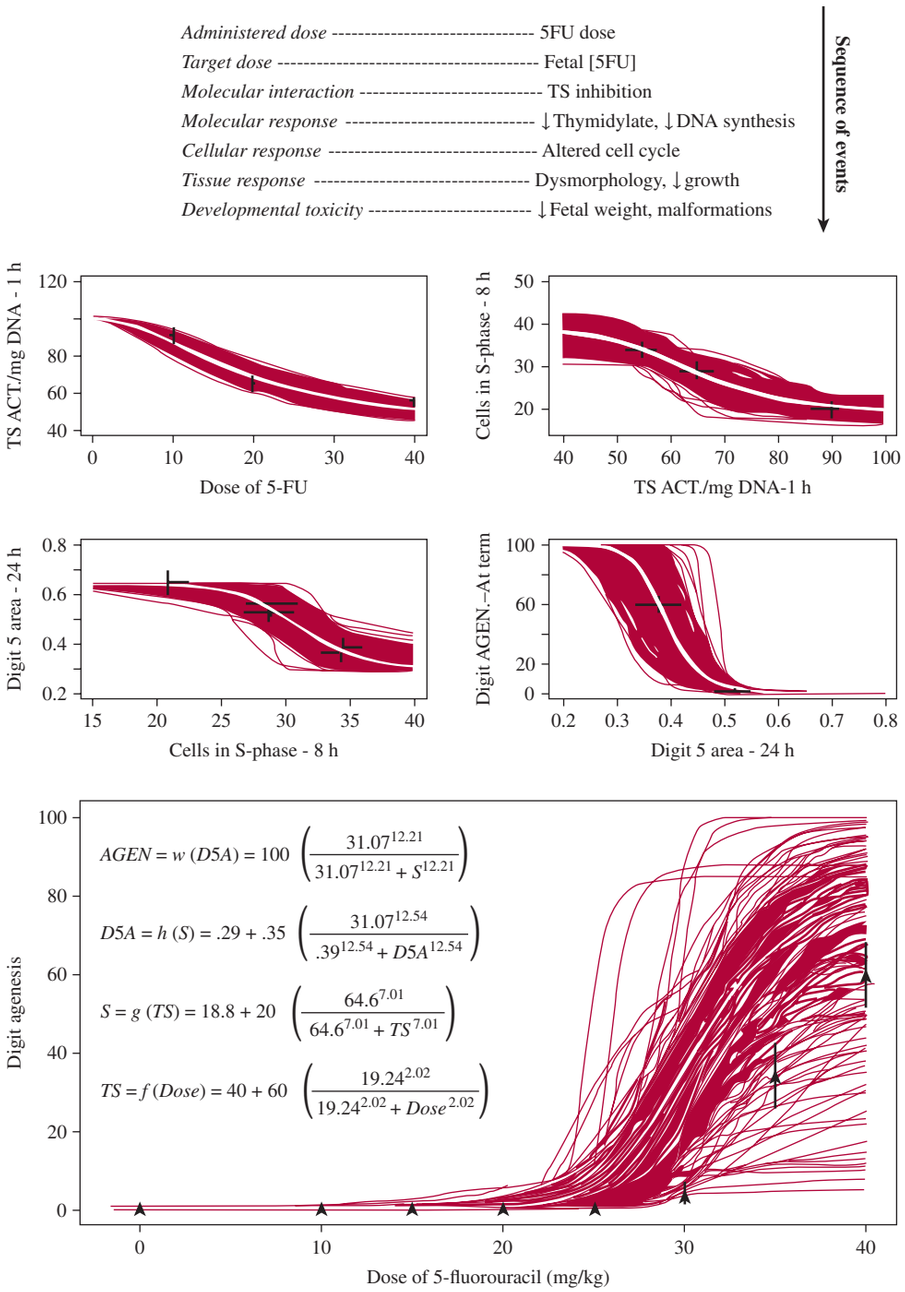

Figure 10-11. *Biologically based dose–response modeling of the developmental toxicity of 5-fluorouracil (5-FU) following maternal administration of gestation day 14 in the rat. Top:* Proposed model for the developmental toxicity of 5-FU based on thymidylate synthetase (TS) inhibition, decreased DNA synthesis, cell cycle alterations, growth deficits, and hind-limb dysmorphogenesis. *Middle:* Relationships between successive endpoints are shown in these four panels (hind-limb-bud TS activity vs. 5-FU dose, S-phase accumulation vs. TS activity, limb digit 5 area at 24 hours postdose vs. proportion of cells in S-phase, and digit dysgenesis at term vs. digit 5 area at 24 hours). Data were fitted with Hill equations. The curves were generated by Monte Carlo simulation to estimate variability around the predicted relationships. *Bottom:* Integrated model for the induction of hind-limb defects by 5-FU, generated by integration of the individual Hill equations describing the relationships between successive model endpoints as presented in the middle panels. Individual equations are listed and the curves are the results of Monte Carlo simulations of the whole sequence of event relationships. Results indicate that variability in the intermediate events can account for differences between the actual and predicted dose responses. AGEN, digit agenesis at term; D5A, digit 5 area at 24 hours; S, percent of cells in S-phase. (Adapted from Shuey et al. [1994]; images courtesy of Dr Woodrow Setzer.)

parameters. Understanding the mode of action for any developmental toxicant can greatly inform the human risk assessment process. Although the construction of BBDR models exemplifies the extent of sophistication and quantification to which such exercises can be pursued, even more qualitative information on modes of action can have a great impact on the interpretation of developmental toxicity test results. For excellent examples of the utility of mode of action information, the reader is referred to an issue of *Critical Reviews in Toxicology* (35[September–October], 2005) devoted to this topic. Developmental toxicants for which mode of action is discussed include ethylene glycol (Corley et al., 2005), nicotine (Slikker et al., 2005), phthalate esters (Foster, 2005), vinclozolin (Kavlock and Cummings, 2005), valproic acid (Wiltse, 2005), hemoglobin-based oxygen carriers (Holson et al., 2005), angiotensin-converting enzyme inhibitors (Tabacova, 2005), and propylthiouracil (Zoeller and Crofton, 2005).

The evolution of mechanistic modeling of adverse toxicological outcomes has led to the concept of adverse outcome pathways (AOPs), which are chemical-agnostic descriptions of the etiology of an adverse apical outcome such as a birth defect (Edwards et al., 2016). They are similar to BBDR models except that the chemical or agent that causes the adverse effect is not stipulated. The first step in an AOP is called the molecular initiating event, which occurs at the first interaction of the toxic moiety with the cell or organism. With adequate initiation, this is followed by a pathogenic series of key events leading to an adverse outcome. The BBDR model for 5-FU in essence contains an AOP, in which inhibition of thymidylate synthetase is the initiating event, digit agenesis is the adverse outcome, and reduced DNA synthesis and cell cycle blockage are key events. The quantitative relationships between key events are called key event relationships, represented in the 5-FU BBDR model by the Hill equations shown in Fig. 10-11.

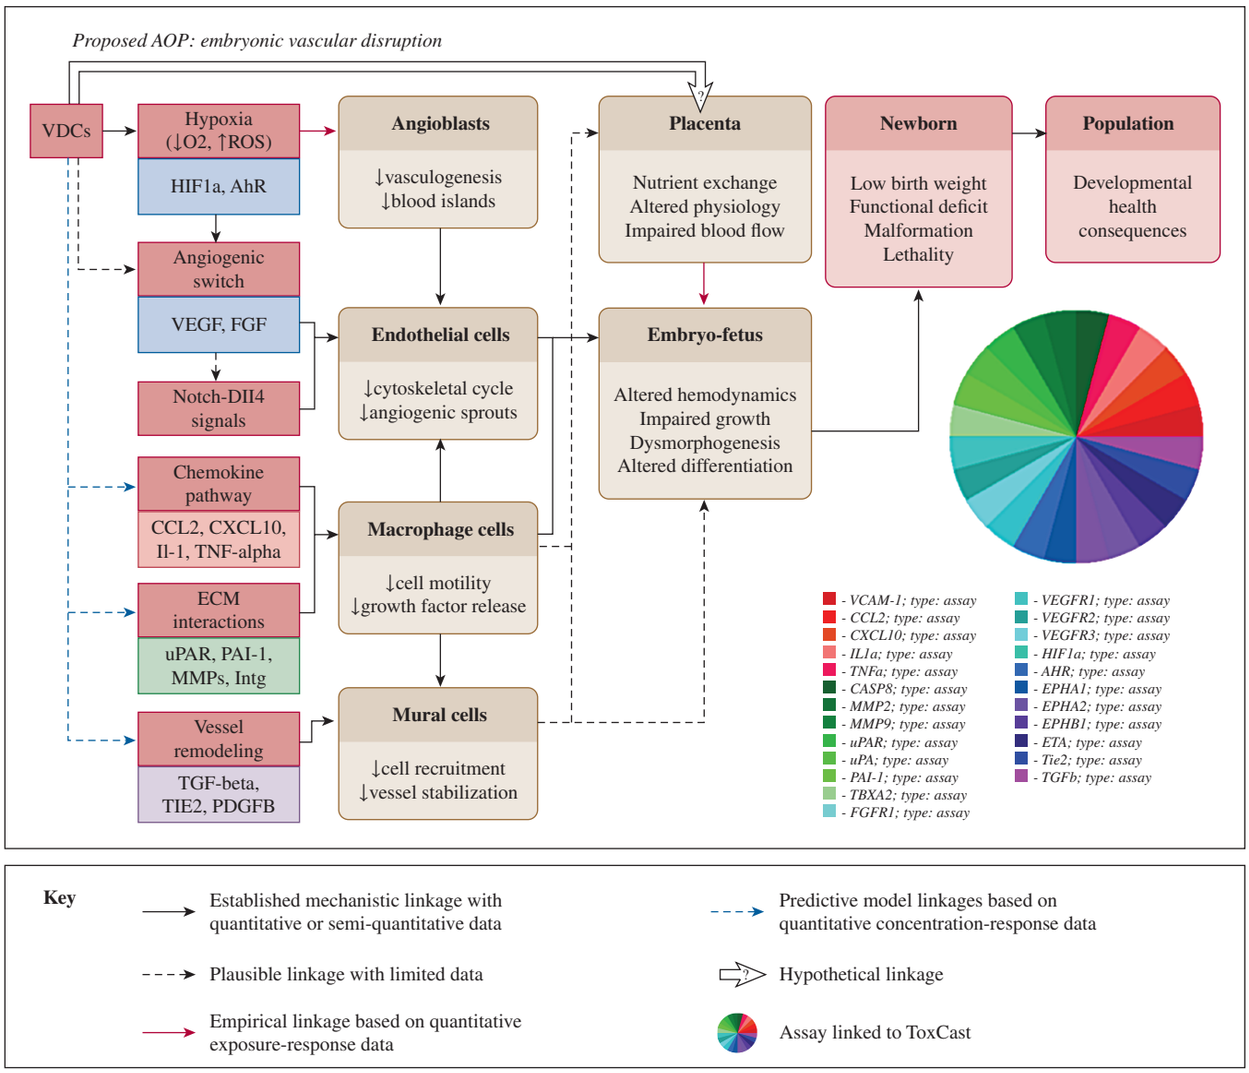

Figure 10-12. *Adverse outcome pathway (AOP) for embryonic vascular disruption.* This AOP for embryonic vascular disruption was built using high-throughput screening data from the EPA's ToxCast database. Anchor 1 (red boxes on the left side) addresses macromolecular interactions of the toxicant with elements of the pathway. Anchor 2 (red boxes on the right) refer to relevant organismal and population responses. The middle columns address intervening cellular and organ responses. The color wheel indicates sectors for 25 ToxCast assays shown that had evidence of abnormal embryonic vascular development based on genetic mouse models and mapped to previously identified critical pathways. VDC, vascular disrupting chemical. (Adapted from Knudsen and Kleinstreuer [2011].)

PATHWAYS TO THE FUTURE

In 2000, a committee assembled by the National Research Council (NRC) released its report, *Scientific Frontiers in Developmental Toxicology and Risk Assessment* (NRC, 2000), which concluded that major discoveries have been made about mechanisms of normal development that have been conserved in diverse animals. Many of these animals have been used extensively in developmental biology and genetics, including the fruit fly, roundworm, zebrafish, frog, chick, and mouse. That these key pathways have been preserved over millions of years of evolution and speciation provides a strong scientific rationale for using these animal models for developmental toxicology. These organisms are advantageous for developmental toxicity studies due to their well-known genetics and embryology, their rapid generation time, and the ability to manipulate their genetics to probe specific developmental pathways or to incorporate human genes, such as those of drug metabolizing enzymes, to answer questions of interspecies extrapolation. As discussed above, there has been a great deal of progress toward using alternative approaches for evaluating developmental toxicity. A landmark NRC report entitled *Toxicity Testing in the 21st Century: A Vision and Strategy* (NRC, 2007) laid out an approach toward revolutionizing the way that toxicity is assessed, moving from expensive and time-consuming animal studies to high-throughput in vitro assays

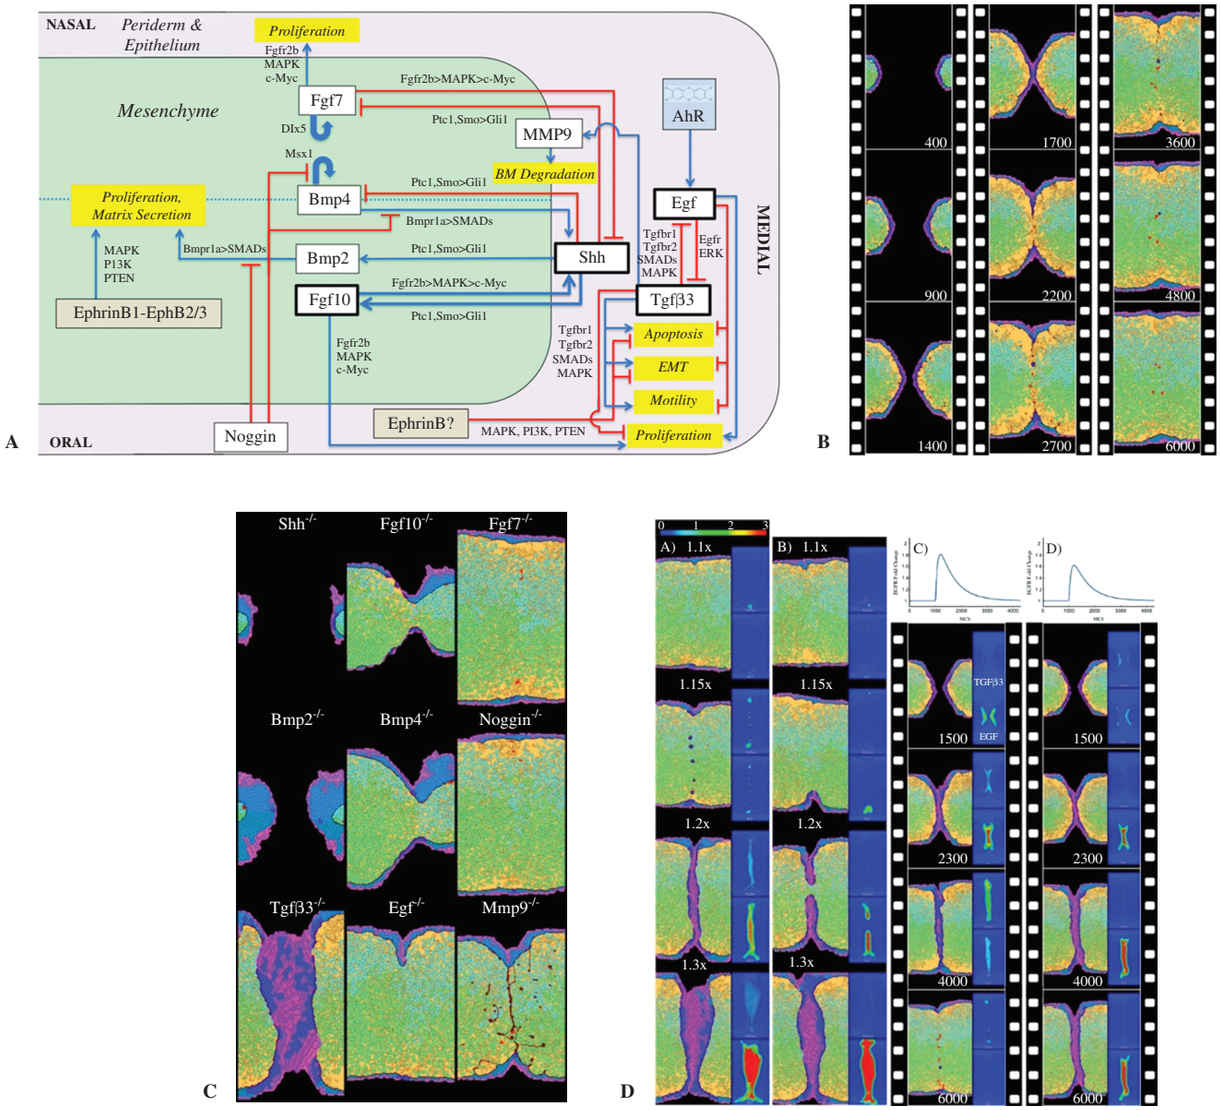

Figure 10-13. *Computational agent–based model of normal palate development and effects of virtual gene knockout or chemical toxicity.* Temporally, the model begins with the palatal shelves elevated to the horizontal position. The model includes mesenchymal, epithelial, and periderm cells, as well as basement membrane and extracellular matrix. **A**. Signaling pathways and molecules incorporated into the model and driving cellular (agent) behavior and interactions. **B.** Model simulation of normal palatogenesis, exhibiting growth (*left column top to bottom*), medial contact of the palatal shelves (*middle column top to bottom*), and dissolution of the medial edge epithelium and fusion of the shelves (*right column top to bottom*). **C.** Effects of virtual (computational) knockout of the various signaling molecules shown in panel A. Effects range from lack of growth to lack of fusion to incomplete fusion to normal fusion. **D**. Simulated fusion defects induced by TCDD exposure via AhR-mediated fold changes in EGFR (fold changes indicated in columns A and B) and by all-trans retinoic acid (columns C and D) displayed for time-dependent changes in EGFR. (Adapted from Hutson et al. [2017].)

based on cellular toxicity pathways and analyzing outputs using a systems biology approach. This report in part formed the basis for the EPA's ToxCast program discussed earlier, including assays relevant to developmental toxicity. While full implementation of such approaches is still years away, in the interim these assays are beginning to provide data for prioritizing chemicals for further study.

Advances in Genomics, Proteomics, Metabolomics, and Bioinformatics

As our knowledge of the genetic and epigenetic control of normal development has advanced immensely in the 21st century, so has the technology to examine gene expression and its control, networks of interrelated gene products, and changes in gene expression induced by alterations in the developmental environment. Advances in genomics, proteomics, metabolomics, and bioinformatics are being used to advance our understanding of health and disease, including normal and abnormal development. The ability to gather and analyze large amounts of biological data using databases and models of biological systems allows a more comprehensive approach to understanding pathways to developmental toxicity. Systems modeling and virtual tissues are among the nascent cutting-edge approaches being developed (Knudsen and Daston, 2010). An excellent example is the modeling of a proposed AOP for embryonic vascular disruption (Knudsen and Kleinstreuer, 2011). The model includes a number of potentially responsive gene networks involved in responses to hypoxia, the angiogenic switch, extracellular matrix interactions, and vessel remodeling, as well as predicted downstream consequences of disrupting these networks (Fig. 10-12). Further work on mechanisms underlying vascular dysgenesis during development can be found in Kleinstreuer et al. (2011) and Ellis-Hutchings et al. (2017).

Computational and Organotypic Models of Developing Systems

Much like the programs that allow a computer to play chess at a high level, software is being developed that can recapitulate development of tissues and organs based on the properties and relationships of cells. These so-called agent-based models (the cell is the agent) allow dynamic interactions among cells that through simulated morphogenesis can build good facsimiles of embryological structures. These models contain signaling pathways, receptors, and extracellular matrices that invoke specific cell behaviors such as adhesion, migration, mitosis, apoptosis, and differentiation. An excellent example is the recent development of a computational model of secondary palate fusion and cleft palate pathogenesis (Hutson et al., 2017) (Fig. 10-13). Signaling pathways underlying palate development are well understood and include TGF-β, BMP, FGF, EGF, SHH, noggin, and ephB. This signaling network drives the virtual palate model as diagrammed in Fig. 10-13A. The model begins at the prefusion stage at which the palatal shelves have elevated to the horizontal position, and the shelves consist of mesenchyme, basal epithelium and periderm, basement membrane, and extracellular matrix. The signaling pathways and gradients drive growth and fusion through contact of the medial edge epithelia and dissolution of the medial edge seam (Fig. 10-13B). Computational gene knockouts of signaling molecules can be executed to observe effects on phenotype (Fig. 10-13C), and predictions of the effects of chemical exposure during palatogenesis can be made based on knowledge of the underlying mechanisms of toxicity (Fig. 10-13D).

In vitro techniques for developmental toxicology and other disease studies are rapidly progressing from two-dimensional cell culture systems to complex three-dimensional "organoid" cultures (Schweiger and Jensen, 2016; Belair and Abbott, 2017). This approach promises to provide systems that have adequate complexity to recapitulate facets of morphogenesis from precursor cells not possible in current two-dimensional cell cultures. Several groups are currently developing these "organ-on-a-chip" models of organogenesis.

BLOOD AS A TARGET ORGAN

Hematotoxicology is the study of adverse effects of chemicals, including pharmaceutical drugs, on the blood and blood-forming tissues. The vital functions that blood cells perform, together with the susceptibility of this highly proliferative tissue to intoxication, make the hematopoietic system unique as a target organ. Accordingly, hematotoxicity ranks alongside toxicity to the liver and kidney as among the most important considerations in assessing risks to humans from pharmaceutical, occupational, and environmental chemical exposures.

The blood can be considered as a tissue in its own right, as it comprises around 7% of the body weight of a typical adult who has 4.7 to 5.5 L of blood. Some of the vital functions that the blood performs include the delivery of oxygen to tissues throughout the body, maintenance of vascular integrity, and provision of the many affector and effector immune functions necessary for host defense. All of these functions require a prodigious proliferative and regenerative capacity. Each of the various blood cells (erythrocytes, granulocytes, and platelets) is produced at a rate of approximately 1 to 3 million/s in a healthy adult and several times that rate in conditions where demand for these cells is high, as in hemolytic anemia or suppurative inflammation (Kaushansky, 2006). As with intestinal mucosa and gonads, this characteristic makes hematopoietic tissue a particularly sensitive target for cytoreductive or antimitotic drugs, such as those used to treat cancer, infection, and immune-mediated disorders. This tissue is also susceptible to secondary effects of toxic chemicals that affect the supply of nutrients, such as iron; the clearance of toxicants and metabolites, such as urea; or the production of vital growth factors, such as erythropoietin and granulocyte colony-stimulating factor (G-CSF).

The consequences of direct or indirect damage to blood cells and their precursors are predictable and potentially life-threatening. They include hypoxia, hemorrhage, and infection. These effects may be subclinical and slowly progressive or acute and fulminant, with dramatic clinical presentations. In cancer treatment and other clinical settings, hematotoxicity is usually assessed in the context of risk versus benefit. It may be used to define dosage in treatment modalities in which these effects are limiting, such as those employing certain anticancer, antiviral, and antithrombotic drugs.

While limited hematotoxicity may be an unavoidable side effect of treatments for serious illnesses, it is unacceptable in treatments for less serious illnesses, such as mild hypertension or arthritis, or following exposure to contaminated foods or environmental contaminants. Risk-versus-benefit decisions involving hematotoxicity may be controversial, especially when the incidence of these effects is very low. Irrespective of whether the effect is linked to the pharmacologic action of the drug, as with cytoreductive or thrombolytic agents, or unrelated to its intended action, the right balance between risk and benefit is not always clear.

Hematotoxicity may be regarded as *primary,* where one or more blood components are directly affected, or *secondary,* where the toxic effect is a consequence of other tissue injury or systemic disturbances. Primary toxicity is regarded as among the more common serious effects of xenobiotics, particularly drugs (Vandendries and Drews, 2006). Secondary toxicity is exceedingly common, due to the propensity of blood cells to reflect a wide range of local and systemic effects of toxicants on other tissues. These secondary effects on hematopoietic tissue are often more reactive or compensatory than toxic, and provide the toxicologist and clinician with an important and accessible tool for monitoring and characterizing toxic responses.

HEMATOPOIESIS: THE FORMATION OF THE BLOOD CELLULAR COMPONENTS

The production of blood cells, or hematopoiesis, is a highly regulated sequence of events by which blood cell precursors proliferate and differentiate to meet the relentless needs of oxygen transport, host defense and repair, hemostasis, and other vital functions described previously. The bone marrow is the principal site of hematopoiesis in humans and most laboratory and domestic animals. However, the lung has also recently been shown to be a major site of hematopoiesis and harbors blood stem cells that can repopulate the bone marrow (Lefrancais et al., 2017). The spleen has little function in blood cell production in the healthy human but plays a critical role in the clearance of defective or senescent cells, as well as in host defense. In the human fetus, hematopoiesis can be found in the liver, spleen, bone marrow, thymus, and lymph nodes. The bone marrow is the dominant hematopoietic organ in the latter half of gestation and the major blood-cell-producing organ at birth (Moore, 1975). All marrow is active, or "red marrow," at birth (Hudson, 2006). During early childhood, hematopoiesis recedes in long bones and, in adults, is confined to the axial skeleton and proximal humerus and femur (Custer and Ahlfeldt, 1932). The marrow in the distal long bones becomes "yellow" or fatty. When demand for blood cell production is great, as with certain disease states, fatty marrow can be reactivated as sites of hematopoiesis (Fig. 11-1). This can be useful in toxicology studies as a marker of sustained hematopoietic stress, as exemplified in studies on the hematopathology of cephalosporin toxicity in the dog (Bloom et al., 1987). Under extreme conditions, embryonic patterns of hematopoiesis may reappear as *extramedullary hematopoiesis* (Young and Weiss, 1997).

While the central function of bone marrow is hematopoiesis and lymphopoiesis, bone marrow is also one of the sites of the mononuclear phagocyte system (MPS), contributing monocytes that differentiate into a variety of MPS cells located in liver (Kupffer cells), spleen (littoral cells), lymph nodes, and other tissues. Conventional histologic and cytologic sampling of bone marrow reveals a very limited picture of an exceedingly complex tissue containing erythroid, granulocytic, megakaryocytic, MPS, and lymphoid precursors in varied stages of maturation; stromal cells; and vasculature all encased by bone (Fig. 11-1). Routine examinations of such specimens in the laboratory cannot possibly reveal the sophisticated interactions that mediate lineage commitment, proliferation, differentiation, acquisition of functional characteristics, and trafficking that result in the delivery of mature cells to the circulation, as required in sickness and in health. Hematopoietic stem cells (HSCs) reside in bone marrow niches, specialized microenvironments that include a range of types of support cells including mesenchymal stromal cells, vascular endothelial cells, and non-myelinating Schwann cells that interact with HSC. Together with osteoblasts, macrophages, and megakaryocytes, these support cells regulate HSC fate, including quiescence or proliferation and differentiation in response to dynamic physiological and pathological states (Morrison and Scadden, 2014; Asada et al., 2017). HSC regulation is mediated by complex interactions among transmembrane receptors, secreted factors, and extracellular matrix molecules (Domingues et al., 2017a). CXCL12 (also known as stromal cell-derived factor-1, SDF-1), produced by mesenchymal stromal cells, vascular cells, and osteoblasts, is a key regulator of HSC maintenance proliferation and migration, via its receptor CXCR4, as reviewed (Nagasawa, 2015). Other important growth factors include niche-derived transforming growth factor-1 (TGF-β1), stem cell factor (SCF), and thrombopoietin (TPO), the latter produced by megakaryocytes. Receptors and cell adhesion molecules (including cadherins, selectins, and integrins) are expressed by HSC and interact with extracellular matrix components (such as fibronectin, laminin, and collagen) and with other niche cells. Signaling via the aryl hydrocarbon receptor (AhR) expressed on HSC is an important regulator of hematopoiesis and prolonged and/or inappropriate stimulation of AhR activity was proposed to disrupt the regulation of HSCs (Gasiewicz et al., 2014). Other signaling pathways, notably Wnt/β-catenin, also regulate stem cell growth, function, and death (Ahmadzadeh et al., 2016). Earlier studies assessed HSC activity by testing for blood cell repopulation in an animal following irradiation. Newer methodologies such as monoclonal antibodies and fluorescence activated cell sorting (FACS) enable the purification of hematopoietic stem and progenitor cells (HSPCs) on the basis of cell surface markers.

All of the cellular components of the blood are derived from pluripotent HSCs (Fig. 11-2). This leads to a hierarchical model of hematopoiesis in which HSCs differentiate into common myeloid progenitors (CMPs) and common lymphoid progenitors (CLP) that ultimately generate the entire range of mature blood cells. CLPs give rise to B cells, T cells, and natural killer (NK) cells. CMPs differentiate into platelets (also known as thrombocytes), erythrocytes, and mast cells and into myeloblast cells that give rise to monocytes (which ultimately become macrophages), neutrophils, basophils, and eosinophils.

As reviewed by Seita and Weissman (Seita and Weissman, 2010), hematopoiesis is more complex than illustrated in Fig. 11-2. HSCs have self-renewal capability and they give rise to multipotent progenitors (MPPs) that lack self-renewal capability. HSCs, progenitors, and other cells in the hierarchy can be identified by antibodies directed against distinct combinations of cell surface antigens in a process known as immunophenotyping. Coupling of the antibodies to fluorescent markers enables fluorescent-activated cell sorting (FACS). The markers distinguishing cells in the mouse and human hierarchies were previously summarized, for example, human HSCs were characterized as $Lin^{-}CD34^{+}CD38^{-}CD90^{+}CD45RA^{-}$ and MPPs as $Lin^{-}CD34^{+}CD38^{-}CD90^{-}CD45RA^{-}$ (Seita and Weissman, 2010), but refinements continue to be made, as reviewed (McCracken et al., 2016).

A variety of suffixes are commonly used in describing altered hematopoiesis. These include -emia, with reference to the blood (e.g., uremia, septicemia, anemia); -penia, decreased number of blood cells (e.g., leukopenia, pancytopenia); -cytosis, increased number of blood cells (e.g., granulocytosis, thrombocytosis, erythrocytosis).

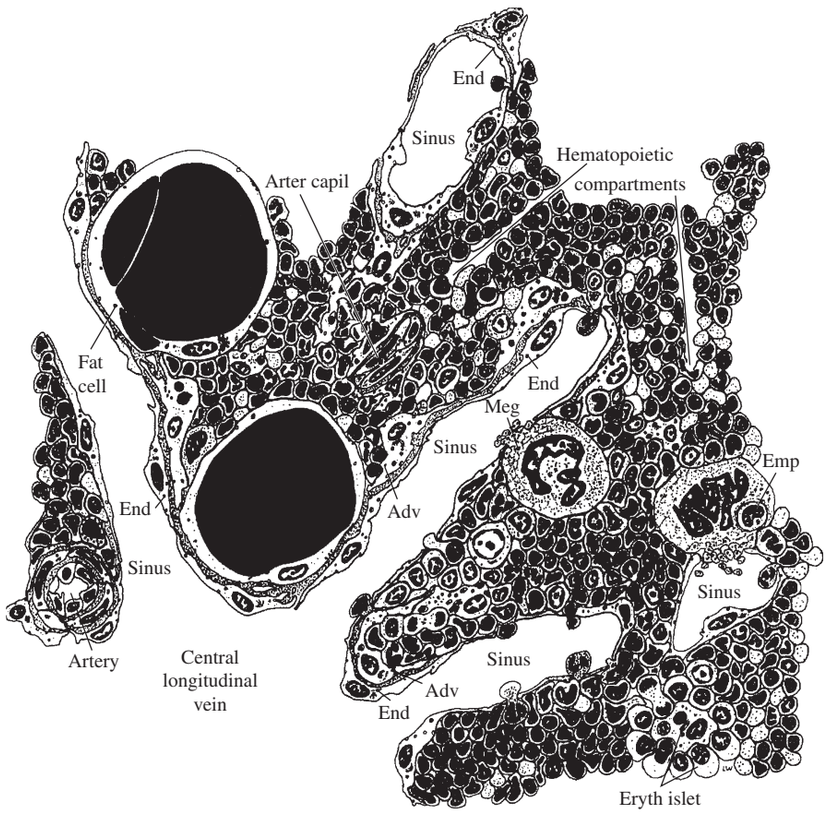

Figure 11-1. *Bone marrow schema.* Several venous sinuses (Sinus), cut longitudinally, drain into the central longitudinal vein, cut in cross-section. A branch of the nutrient artery (Artery) and an arterial capillary (Arter Capil) are present. The circulation in the bone marrow, as in the other tissues of the body save the spleen, is "closed," that is, there is endothelial continuity from artery into vein. Veins in bone marrow have in common with veins elsewhere the primary function of returning blood to the heart. Marrow veins, in addition, possess the distinctive function of receiving blood cells produced and stored in the marrow and carrying them to thymus or spleen, or into the general circulation, for further maturation, widespread distribution, and function. The hematopoietic compartments of the bone marrow consist of hematopoietic cells in varying stages of differentiation supported by a fibroblastic stroma. They lie between the most proximal veins, termed venous sinuses or vascular sinuses. When hematopoiesis is rather quiet and few nascent blood cells cross the wall of vascular sinuses, moving from hematopoietic compartments into the sinus lumen, the wall of the sinus tends to be trilaminar, consisting of endothelium (end), wispy basement membrane (in stipple), and adventitial reticular cells (adv) that form an incomplete outermost layer and branch out into the hematopoietic compartment, forming a scaffolding enclosing and supporting the hematopoietic cells. Thus, adventitial reticular cells are both vascular, as the outermost wall of the vascular sinus, and stromal, branching into the perivascular hematopoietic space, holding the vascular sinus in place and supporting hematopoietic cells. Where hematopoietic cell traffic across the wall of the venous sinus is heightened, the adventitial cell cover is retracted and a larger expanse of endothelium, covered only by wisps of basement membrane, is exposed to the hematopoietic cells, facilitating their transmural cell passage. Where transmural cell passage is greatly reduced, adventitial cells accumulate fat and become rounded and bulky, now termed adipocytes, impeding hematopoietic cell passage, and occupying space in the hematopoietic compartment that, when they transform again to adventitial cells flattened upon veins, yield to hematopoiesis. These fibroblastic stromal cells in the marrow of central bones can modulate readily to and from adventitial cell and adipocyte and retain their granulocyte inductive capacities in either form. In the distal limb and tail bones, where there is little hematopoiesis, they assume the adipocyte form in such large numbers that the marrow is grossly yellow. These adipocytes lose fat only in marked hematopoietic stress, as in spherocytic and other severe anemias where this marrow becomes hematopoietic and grossly red. In such stress, moreover, barrier cells may augment or replace adventitial reticular cells and even endothelial cells. Thus, adventitial cells/adipocytes, by their disposition and bulk, mechanically regulate hematopoiesis and blood cell delivery. In addition, they do so in a subtle manner, through paracrine secretion of several small-protein regulatory factors termed cytokines, which include interleukins. (Reprinted from Young and Weiss [1997], with permission from the authors and Elsevier Science.)

TOXICOLOGY OF THE ERYTHRON

The erythron (pronounced: er´ĭthron) consists of the circulating red blood cells (erythrocytes; RBCs) in the blood, their precursors, and all the body elements concerned in their production.

The Erythrocyte

Erythrocytes make up 40% to 45% of the circulating blood volume and serve as the principal vehicle of transportation of oxygen from the lungs to the peripheral tissues. In addition, erythrocytes are involved in the transport of carbon dioxide from tissues to the lung, maintenance of a constant pH in blood, and regulation of blood flow to tissues (Hsia, 1998; Kim-Shapiro et al., 2005). Erythrocytes also regulate vascular homeostasis through their ability to transport, produce, and secrete the vasoactive compounds nitric oxide (NO) (Porro et al., 2014). Erythrocytes express high levels of complement receptor 1 (CR1), through which they regulate the complement pathway and clear C3-opsonized immune complexes. The number of CR1 molecules is decreased with normal aging of erythrocytes and in systemic lupus erythematosus (SLE), HIV infection, and some hemolytic anemias (Khera and Das, 2009). Erythrocytes can also act as a carrier and/or reservoir for drugs and toxicants (Schrijvers et al., 1999) and are being explored as delivery systems for drugs, biological, and nanoparticles (Villa et al., 2016). The effect of xenobiotics on erythrocytes has been extensively evaluated, because of both the ready access to these cells and the

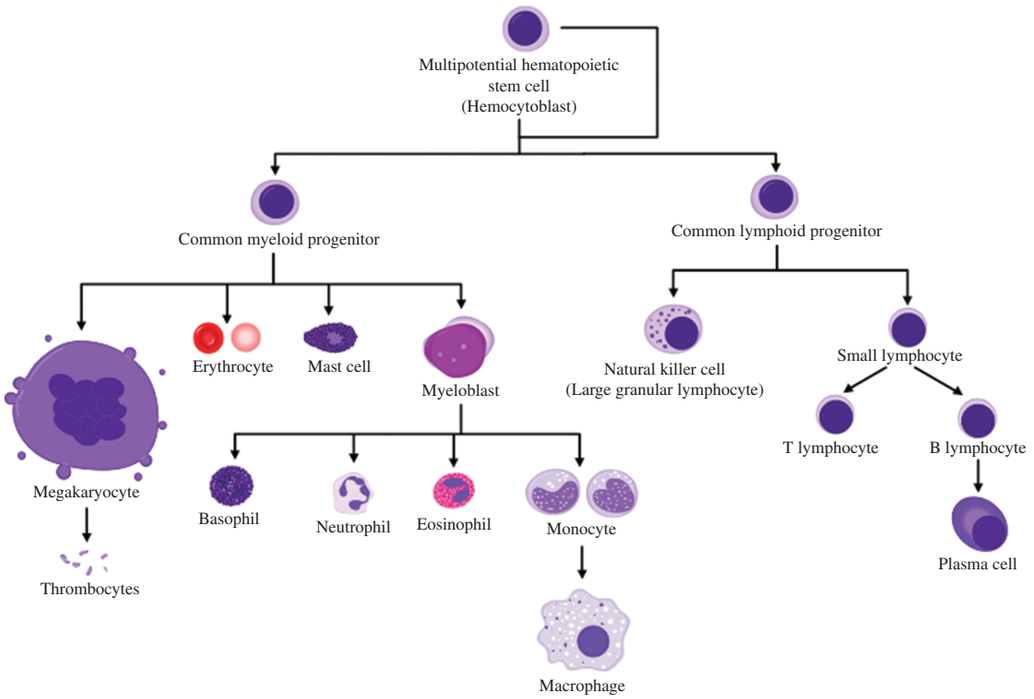

Figure 11-2. *Schematic of hematopoiesis.* All mature blood cells are derived from pluripotent HSCs in a hierarchical process. HSCs differentiate into common myeloid progenitors (CMPs) and common lymphoid progenitors (CLP) that ultimately generate the entire range of mature blood cells. CLPs give rise to B cells, T cells, and natural killer (NK) cells. CMPs differentiate into platelets (also known as thrombocytes), erythrocytes, and mast cells and into myeloblast cells that give rise to monocytes (which ultimately become macrophages), neutrophils, basophils, and eosinophils. Reproduced from Wikimedia Commons.

frequency with which xenobiotics cause changes in these critically important cells.

Xenobiotics may affect the production, function, and/or survival of erythrocytes. These effects are most frequently manifest as a change in the circulating red cell mass, usually resulting in a decrease (anemia). Occasionally, chemicals that increase oxygen affinity lead to an increase in red cell mass (erythrocytosis), which can be caused by polycythemia (an overproduction of RBCs in absence of an appropriate stimulus, e.g., altitude), but this is distinctly less common. However, a known inappropriate chemical stimulus for erythropoiesis is cobalt ion (Davis and Fields, 1958), which induces transcription of erythropoietin gene via activation of hypoxia-inducible factor (Maxwell and Salnikow, 2004). Erythrocytosis caused by polycythemia was commonly seen, along with other symptoms, in the epidemics of beer drinker's cardiomyopathy in the 1960s after cobalt was added into some brands of beer to stabilize foam (Morin et al., 1969). Shifts in plasma volume can alter the relative concentration of erythrocytes/hemoglobin and can be easily confused with true anemia or erythrocytosis.

There are two general mechanisms that lead to true anemia—either decreased production or increased erythrocyte destruction. Both mechanisms may be operative in some disorders, or a combination may arise due to the imposition of a second disorder on a compensated underlying problem. For example, patients with compensated congenital hemolytic anemias are very susceptible to additional insults that may precipitate an acute drop in a previously stable red cell mass, such as parvovirus infection-associated suppression of erythropoiesis.

Evaluation of a peripheral blood sample can provide evidence for the underlying mechanism of anemia. The usual parameters of a complete blood count (CBC)—including the RBC count, hemoglobin concentration (Hbg), and hematocrit (also referred to as packed cell volume [PCV])—can establish the presence of anemia. Two additional parameters helpful in classifying an anemia are the mean corpuscular volume (MCV) and the reticulocyte count. Increased destruction is usually accompanied by an increase in reticulocytes (young erythrocytes containing residual RNA), which are easily enumerated. Reticulocyte counting may also be useful in conditions associated with decreased production, particularly when assessing response to therapy. Other readily performed parameters helpful in the evaluation of the human erythron include erythrocyte morphology (e.g., megaloblastic changes, erythrocyte fragmentation, sickled RBCs); serum concentration of haptoglobin, lactate dehydrogenase, free hemoglobin, vitamin B_{12}, folate, iron, and ferritin; direct and indirect red cell antiglobulin tests; and bone marrow morphology (Prchal, 2006; Ryan, 2006). Newer techniques to evaluate erythrocyte function include time-lapse interferometry to quantify membrane fluctuations at the nanometer scale and thus cell stiffness (Bhaduri et al., 2014) and metabolomics (Srivastava et al., 2017).

Alterations in Red Cell Production

Erythrocyte production is a continuous process that is dependent on frequent cell division and a high rate of hemoglobin synthesis. Human adult hemoglobin (hemoglobin A), the major constituent of the erythrocyte cytoplasm, is a tetramer composed of two α-globin and two β-globin chains, each with a heme residue located in a stereospecific pocket of the globin chain. Synthesis of hemoglobin is dependent on coordinated production of globin chains and heme moieties. Abnormalities that lead to decreased hemoglobin synthesis are relatively common (e.g., iron deficiency) and are often associated with a decrease in the MCV and hypochromasia (increased central pallor of RBCs on stained blood films due to the low hemoglobin concentration).

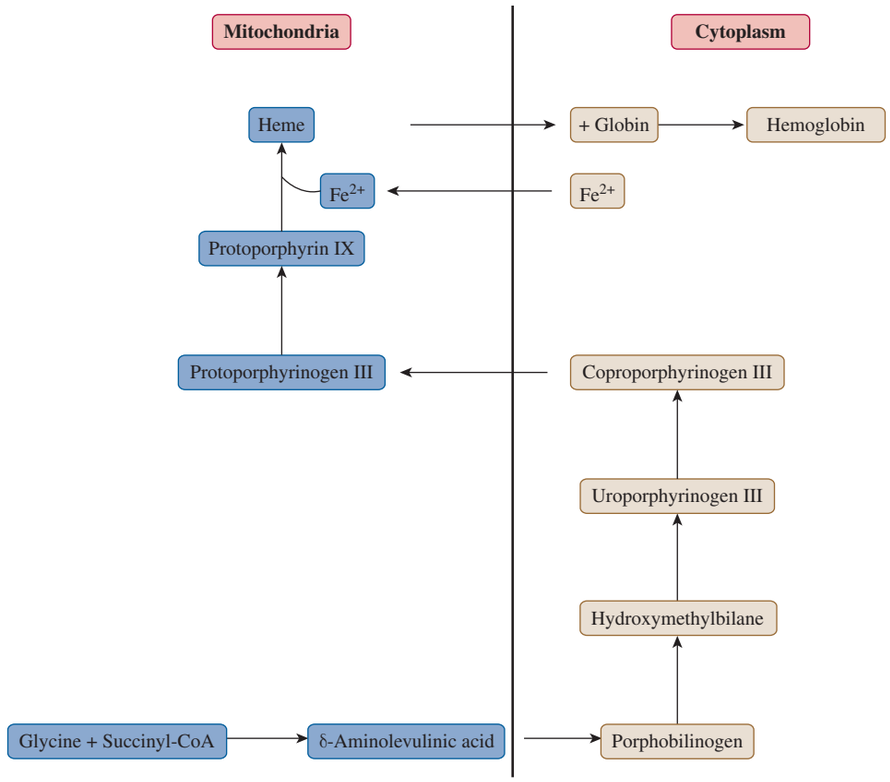

Figure 11-3. *The synthesis of heme involves a series of reactions that occur in the cytoplasm and mitochondria of erythroblasts.* The initial step in the pathway is the mitochondria synthesis of δ-aminolevulinic acid, a step that is commonly affected by xenobiotics, including lead. Ferrochelatase catalyzes the incorporation of ferrous iron into the tetrapyrrole protoporphyrin IX. Inhibition of the synthetic pathway leading to protoporphyrin IX, as occurs in the sideroblastic anemias, can cause an imbalance between iron concentration and ferrochelatase activity, resulting in iron deposition within mitochondria. Mitochondrial accumulation of iron is the hallmark lesion of the sideroblastic anemias.

An imbalance between α- and β-chain production is the basis of congenital thalassemia syndromes and results in decreased hemoglobin production and microcytosis (Weatherall, 2006). Xenobiotics can affect globin chain synthesis and alter the composition of hemoglobin within erythrocytes. The most well-known example is hydroxyurea, which increases the synthesis of γ-globin chains. The γ -globin chains are a normal constituent of hemoglobin during fetal development, replacing the β chains in the hemoglobin tetramer (hemoglobin F, $\alpha_2\ \gamma_2$). Hemoglobin F has a higher affinity for oxygen than hemoglobin A and can protect against crystallization (sickling) of deoxyhemoglobin S in sickle cell disease (Steinberg, 2006).

Synthesis of heme requires incorporation of iron into a porphyrin ring (Fig. 11-3) (Ponka, 1997; Napier et al., 2005). Iron deficiency is usually the result of dietary deficiency or increased blood loss. Drugs that contribute to blood loss, such as nonsteroidal anti-inflammatory drugs, with their increased risk of gastrointestinal ulceration and bleeding, may potentiate the risk of developing *iron deficiency anemia.* Defects in the synthesis of porphyrin ring of heme can lead to *sideroblastic anemia,* with its characteristic accumulation of iron in bone marrow erythroblasts. The accumulated iron precipitates within mitochondria in a complex with mitochondrial ferritin, causing the characteristic staining pattern of ringed sideroblasts evident on iron stains such as Prussian blue (Cazzola et al., 2003). A number of xenobiotics (Table 11-1) can interfere with one or more of the steps in erythroblast heme synthesis and result in sideroblastic anemia (Fiske et al., 1994; Alcindor and Bridges, 2002; Beutler, 2006a, 2006b, 2006c). The most well-known of these is lead, which inhibits two enzymes in the heme synthesis pathway, aminolevulinic acid dehydratase (ALAD) and ferrochelatase (Fig. 11-3).

Table 11-1

Xenobiotics Associated with Sideroblastic Anemia

Ethanol	Chloramphenicol
Isoniazid	Copper chelation/deficiency
Pyrazinamide	Zinc intoxication
Cycloserine	Lead intoxication

Hematopoiesis requires active DNA synthesis and frequent mitoses. Folate and vitamin B_{12} are necessary to maintain synthesis of thymidine for incorporation into DNA (Fig. 11-4). Deficiency of folate and/or vitamin B_{12} results in *megaloblastic anemia,* with its characteristic morphologic and biochemical changes (Table 11-2), which commonly affect erythroid, myeloid, and megakaryocytic lineages. A number of xenobiotics may contribute to a deficiency of vitamin B_{12} and/or folate (Table 11-3), leading to megaloblastic anemia. Drugs that cause megaloblastic anemia have a number of different mechanisms of action including modulation of purine metabolism, interference with pyrimidine synthesis, decreased absorption of folic acid, folate analogue activity, decreased absorption of vitamin B_{12}, and increased excretion of vitamin B_{12} (Hesdorffer and Longo, 2016).

Many of the antiproliferative drugs used in the treatment of malignancy predictably inhibit hematopoiesis, including

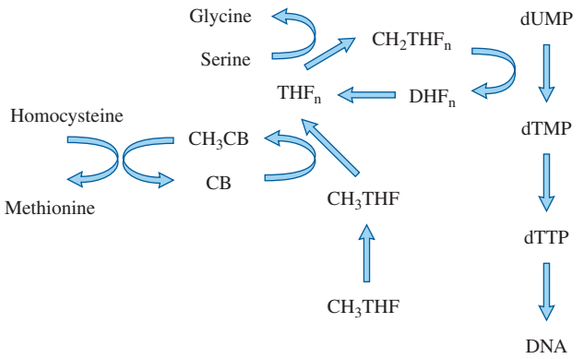

Figure 11-4. *Both tetrahydrofolate (THF) and cobalamin (CB, or vitamin B12) are necessary for the synthesis of thymidine (dTMP) for incorporation into DNA.* Folate enters the cell as a monoglutamate (CH_3THF) but is transformed to a polyglutamate within the cell, a step that helps prevent leakage of folate back across the cell membrane. However, CH_3THF cannot be conjugated with glutamate. CB is necessary for demethylation of the folate, allowing formation of conjugated (polyglutamate) folate (THF_n). In the absence of CB, folate levels within the cell drop, causing a functional deficiency of folate and impairing synthesis of thymidine.

Table 11-2

Laboratory Features of Megaloblastic Anemia

MORPHOLOGY	BIOCHEMISTRY
Peripheral blood	Peripheral blood
Pancytopenia	Decreased B_{12} and/or folate
Macrocytosis (↑ MCV)	Increased LD
Oval macrocytes	Antiparietal cell antibodies
Hypersegmented neutrophils	Antibody to intrinsic factor
Variation in RBC shape	Increased serum iron
Bone marrow	Hypokalemia
Erythroid hyperplasia	
Megaloblastic anemia	
Giant band neutrophils	
Giant metamyelocytes	

erythropoiesis. The resulting bone marrow toxicity may be dose-limiting, as previously discussed. Drugs, such as amifostine, have been developed that may help protect against the marrow toxicity of these drugs (Phillips, 2002). Amifostine protects cells by quenching free radicals, promoting DNA repair by donating hydrogen, and inducing cellular hypoxia (Kouvaris et al., 2007).

Drug-induced *aplastic anemia* may represent either a predictable or idiosyncratic reaction to a xenobiotic. This life-threatening disorder is characterized by peripheral blood pancytopenia, reticulocytopenia, and bone marrow hypoplasia (Young, 1999, 2000; Vandendries and Drews, 2006). Agents such as benzene and radiation have a *predictable* effect on hematopoietic progenitors, and the resulting aplastic anemia corresponds to the magnitude of the exposure to these agents (Smith, 2010). In contrast, idiosyncratic aplastic anemia does not appear to be related to the dose of the agent initiating the process. A long list of chemicals has been associated with the development of aplastic anemia (Table 11-4), many of which have been reported in only a few patients and their association is tentative. The principal mechanisms of aplastic anemia, as with the more common agranulocytosis, are still debated.

Table 11-3

Xenobiotics Associated with Megaloblastic Anemia

B_{12} DEFICIENCY	FOLATE DEFICIENCY
Colchicine	Ampicillin
Cycloserine	Antimetabolites
Ethanol	Chloramphenicol

Thioguanine	Hydroxyurea
Mercaptopurine	Methotrexate
Fludarabine	Mercaptopurine
Pentostatin	Fluorouracil
Methotrexate	Nitrous Oxide

Immune mechanisms have long been thought to contribute to the development of both idiosyncratic disorders, as discussed in greater detail in the next section. However, it has been, up until recently, difficult to obtain definitive evidence for humoral and/or cellular mechanisms of marrow suppression (Young, 2000; Vandendries and Drews, 2006). Both toxicities may be immune-mediated, often involving proteins altered by reactive metabolite–mediated damage (Zhang et al., 2011). Immune-mediated destruction of hematopoietic stem/progenitor cells in aplastic anemia is mediated by a dysregulated T-cell repertoire and abnormal production of cytokines, with individual susceptibility influenced by polymorphisms in cytokine genes and human leucocyte antigen (HLA) alleles (Zeng and Katsanis, 2015).

Pure red cell aplasia is a syndrome in which the decrease in marrow production is limited to the erythroid lineage (Fisch et al., 2000; Djaldetti et al., 2003). It is an uncommon disorder that may be due to genetic defects, infection (parvovirus B19), immune-mediated injury, myelodysplasia, drugs, or other toxins. As pure red cell aplasia occurs sporadically and infrequently, the linkage between drug exposure and pathogenesis of the aplasia remains speculative for some agents. The drugs most clearly implicated and for which there are multiple case reports, include isoniazid (antimycobacterial, anti-tuberculosis), phenytoin (antiepileptic), and azathioprine (immunosuppressant). The mechanism of drug-induced pure red cell aplasia is unknown, but some evidence suggests that it may also be immune-mediated. Patients with drug-induced red cell aplasia should not be reexposed to the purported offending chemical. As noted above, pure red cell aplasia may also occur as a consequence of an immune response to therapeutic erythropoietin.

Alterations in the Respiratory Function of Hemoglobin

Human blood is red in color, ranging from bright red when oxygenated in the arteries to a dark, almost blackish-red when deoxygenated in the veins. It owes its color to hemoglobin, to which oxygen

Table 11-4

Drugs and Other Chemicals Associated with the Development of Aplastic Anemia

Chloramphenicol	Organic arsenicals	Quinacrine
Methylphenylethylhydantoin	Trimethadione	Phenylbutazone
Gold	Streptomycin	Benzene
Penicillin	Allopurinol	Tetracycline
Methicillin	Sulfonamides	Chlortetracycline
Sulfisoxazole	Sulfamethoxypyridazine	Amphotericin B
Mefloquine	Ethosuximide	Felbamate
Carbimazole	Methylmercaptoimidazole	Potassium perchlorate
Propylthiouracil	Tolbutamide	Pyrimethamine
Chlorpropamide	Carbutamide	Tripelennamine
Indomethacin	Carbamazepine	Diclofenac
Meprobamate	Chlorpromazine	Chlordiazepoxide
Mepazine	Chlorophenothane	Parathion
Thiocyanate	Methazolamide	Dinitrophenol
Bismuth	Mercury	Chlordane
Carbon tetrachloride	Cimetidine	Metolazone
Azidothymidine	Ticlopidine	Isoniazid
Trifluoperazine	D-Penicillamine	

binds. Deoxygenated blood is darker due to the difference in color between deoxyhemoglobin and oxyhemoglobin. Hemoglobin is necessary for effective transport of oxygen and carbon dioxide between the lungs and tissues. The respiratory function of hemoglobin has been studied in detail, revealing an intricately balanced system for the transport of oxygen from the lungs to the tissues (Hsia, 1998). Electrostatic charges hold the globin chains of deoxyhemoglobin in a "tense" (T) conformation characterized by a relatively low affinity for oxygen. Binding of oxygen alters this conformation to a "relaxed" (R) conformation that is associated with a 500-fold increase in oxygen affinity. Thus, the individual globin units show cooperativity in the binding of oxygen, resulting in the familiar sigmoid shape to the oxygen dissociation curve (Fig. 11-5). Similarly, the release of the first oxygen molecule facilitates the release of the second, third, and fourth oxygen molecules. The ability of hemoglobin to safely and efficiently transport oxygen is dependent on both intrinsic (homotropic) and extrinsic (heterotropic) factors that affect the performance of this system.

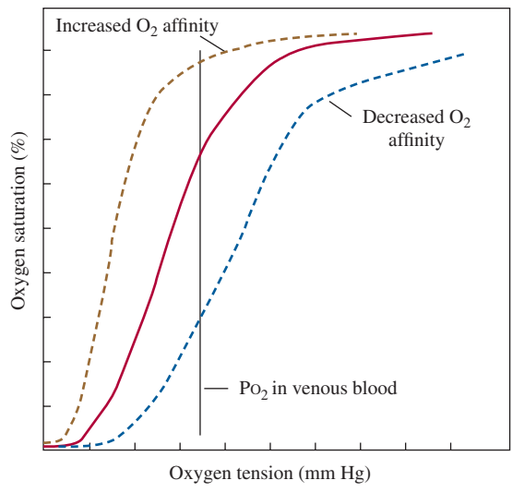

Figure 11-5. *The normal oxygen dissociation curve (solid line) has a sigmoid shape due to the cooperative interaction between the four globin chains in the hemoglobin molecule.* Fully deoxygenated hemoglobin has a relatively low affinity for oxygen. Interaction of oxygen with one heme-iron moiety induces a conformational change in that globin chain. Through surface interactions, that conformational change affects the other globin chains, causing a conformational change in all of the globin chains that increases their affinity for oxygen. Homotropic and heterotropic parameters also affect the affinity of hemoglobin for oxygen. An increase in oxygen affinity results in a shift to the left in the oxygen dissociation curve. Such a shift may decrease oxygen delivery to the tissues. A decrease in oxygen affinity results in a shift to the right in the oxygen dissociation curve, facilitating oxygen delivery to the tissues. In healthy resting adults the extraction of oxygen from capillary blood is about 25%.

Homotropic Effects Leading to Methemoglobinemia One of the most important homotropic properties of oxyhemoglobin is the slow but consistent oxidation of heme iron from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state to form methemoglobin (Percy et al., 2005). The change in oxidation state renders methemoglobin unable to bind and transport oxygen. In addition, the presence of methemoglobin in a hemoglobin tetramer has allosteric effects that increase the affinity of oxyhemoglobin for oxygen, resulting in a leftward shift of the oxygen dissociation curve (Fig. 11-6). The combination of decreased oxygen content and increased affinity may significantly impair delivery of oxygen to tissues when the concentration of methemoglobin rises beyond critical levels (Hsia, 1998; Percy et al., 2005).

Not surprisingly, the normal erythrocyte has metabolic mechanisms for reducing heme iron back to the ferrous state; these mechanisms are normally capable of maintaining the concentration of methemoglobin at less than 1% of total hemoglobin (Percy et al., 2005). In humans, there are two mechanisms by which erythrocytes counteract the formation of methemoglobin. The most predominant is via nicotine adenine dinucleotide (NADH)-methemoglobin reductase (also known as cytochrome b5 reductase), which converts 95% to 99% of methemoglobin to hemoglobin. The second mechanism is via nicotine adenine dinucleotide phosphate (NADPH)-methemoglobin reductase, which requires a cofactor or electron receptor such flavin to reduce methemoglobin. This pathway usually accounts for less than 5% of the reduction of methemoglobin,

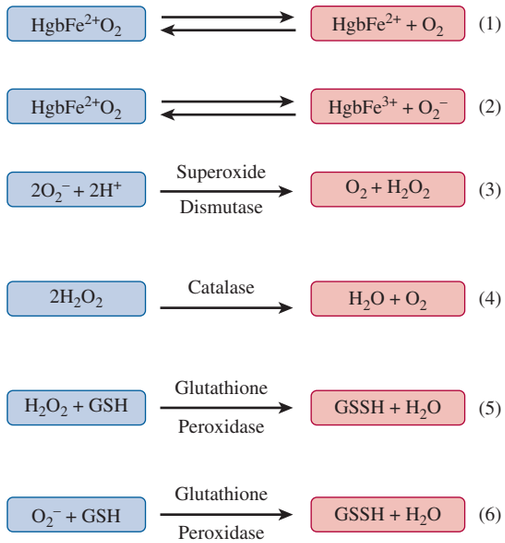

Figure 11-6. *Oxygen normally exchanges with the ferrous iron of deoxyhemoglobin (Eq. (1)).* Oxygen can "capture" one of the iron electrons, resulting in the generation of methemoglobin ($HgbFe^{3+}$) and superoxide (O_2^-) (Eq. (2)). Superoxide must be detoxified or it can lead to oxidative injury within the cell. The pathways involved include superoxide dismutase (Eq. (3)), catalase (Eq. (4)), and glutathione peroxidase (Eqs. (5) and (6)). A supply of reduced glutathione (GSH) is necessary to prevent excessive oxidative injury.

but its activity can be greatly enhanced by methylene blue, which is reduced to leukomethylene blue by NADPH-methemoglobin reductase. Leukomethylene blue then reduces methemoglobin to deoxyhemoglobin.

A failure of these control mechanisms leads to increased levels of methemoglobin, or *methemoglobinemia,* in which the arterial blood becomes a characteristic chocolate-brown color. The most common cause of methemoglobinemia is exposure to an oxidizing xenobiotic that overwhelms the NADH-methemoglobin reductase system. A large number of chemicals and therapeutic agents may cause methemoglobinemia (Table 11-5) (Coleman and Coleman, 1996; Bradberry et al., 2001; Bradberry, 2003). Medications—including local anesthetics, antineoplastic agents, antibiotics, and antimalarials—are the most common cause of methemoglobinemia in clinical practice. Nitrates are present in industrial/household products, in drinking water as a result of fertilizer or animal waste run-off, and in foods such as vegetables and cured meats. Nitrates are toxic through their conversion to nitrate before and/or after ingestion (Greer et al., 2005). Nitrate toxicity can lead to reflex tachycardia and orthostatic hypotension. Infants under 3 months of age are especially susceptible to nitrite-induced methemoglobinemia for several reasons (Greer et al., 2005; Savino et al., 2006). Infants have lower activity of NADH-cytochrome b5 reductase. Gastric pH is lower in infants than in adults enabling increased proliferation of intestinal flora and enhanced conversion of nitrate to nitrite. Nitrites more readily oxidize fetal hemoglobin than adult hemoglobin to methemoglobin. Finally, infants consume large quantities of water relative to their body weight and may have proportionately greater exposures as formula, juices, etc.

The chemicals in Table 11-5 may be divided into direct oxidizers, which are capable of inducing methemoglobin formation when added to erythrocytes in vitro or in vivo, and indirect oxidizers, which do not induce methemoglobin formation when exposed to

Table 11-5

Xenobiotics Associated with Methemoglobinemia

THERAPEUTIC AGENTS	ENVIRONMENTAL AGENTS
Benzocaine	Nitrites
Lidocaine	Nitrates
Prilocaine	Nitrobenzenes
Dapsone	Aniline d+ and aniline derivatives
Amyl nitrate	Butyl nitrite
Isobutyl nitrite	Potassium chlorate
Nitroglycerine	Gasoline additives
Primaquine	Aminobenzenes
Sulfonamide	Nitrotoluenes
Phenacetin	Trinitrotoluene
Nitric oxide	Nitroethane
Phenazopyridine	*ortho*-Toluidine
Metoclopramide	*para*-Toluidine
Flutamide	β-Naphthol disulfonate
Silver nitrate	
Quinones	
Methylene blue	

erythrocytes in vitro but do so after metabolic modification in vivo. Nitrites appear to be able to interact directly with ferrous hemoglobin to facilitate oxidation of heme iron, but the precise mechanism that leads to methemoglobin formation is unknown for many of the other substances listed in Table 11-5.

The development of methemoglobinemia may be slow and insidious or abrupt in onset, as with the use of some topical anesthetics (Shamriz et al., 2014; Tran and Koo, 2014; Barash et al., 2015). Most patients tolerate low levels (<10%) of methemoglobin without clinical symptoms. Cyanosis is often evident when the methemoglobin concentration exceeds 5% to 10%. Levels above 20% are generally clinically significant and some patients may begin to manifest symptoms related to tissue hypoxemia at methemoglobin levels between 10% and 20%. The severity of clinical manifestations increases as the concentration rises above 20% to 30%, with methemoglobin levels above 70% being life-threatening. Intravenous administration of 1 to 2 mg/kg methylene blue is effective in rapidly reversing methemoglobinemia through activation of the NADPH-methemoglobin reductase pathway (Clifton and Leikin, 2003). The effect of methylene blue is dependent on an adequate supply of NADPH. Consequently, methylene blue is not effective in patients with glucose-6-phosphate dehydrogenase (G-6-PD) deficiency because of the decreased capacity to form NADPH (Coleman and Coleman, 1996; Bradberry, 2003).

Methemoglobin can also combine reversibly with a variety of chemical substances, including cyanide, sulfides, peroxides, fluorides, and azides. The interaction of cyanide and methemoglobin is leveraged in two ways. Formation of cyanmethemoglobin by reaction of hemoglobin with potassium ferricyanide is a standard method for measurement of hemoglobin concentration. In the treatment of cyanide poisoning, nitrate is administered to form methemoglobin, which then binds free cyanide, sparing other critical cellular respiratory enzymes such as cytochrome oxidase (Cummings, 2004). Other treatments for cyanide poisoning include sulfur donors (e.g., sodium thiosulfate) and direct binding agents (e.g., hydroxocobalamin), as reviewed (Petrikovics et al., 2015). Regional variations exist in the approach to treatment. In the United States, sodium nitrite and sodium thiosulfate and hydroxocobalamin are favored, while in Europe, hydroxocobalamin is the predominant

treatment. The current approaches have limitations. They are all administered intravenously, limiting their use in a mass exposure event. Sodium nitrate can cause hypotension and methemoglobinemia while sodium thiosulfate has a slow onset of action. Thus, there is a need for newer approaches.

Heterotropic Effects There are three major heterotropic effectors of hemoglobin function: pH, erythrocyte 2,3-bisphosphoglycerate (2,3-BPG, formerly designated 2,3-diphosphoglycerate) concentration, and temperature (Hsia, 1998). A decrease in pH (e.g., lactic acid, carbon dioxide) lowers the affinity of hemoglobin for oxygen, that is, it causes a right shift in the oxygen dissociation curve, facilitating the delivery of oxygen to tissues (Fig. 11-5). As bicarbonate and carbon dioxide equilibrate in the lung, the hydrogen ion concentration decreases, increasing the affinity of hemoglobin for oxygen and facilitating oxygen uptake. Thus, the buffering capacity of hemoglobin also serves to improve oxygen uptake and delivery.

The binding site for 2,3-BPG is located in a pocket formed by the 2 β chains of a hemoglobin tetramer. Binding of 2,3-BPG to deoxyhemoglobin results in stabilization of the "T" conformation, with reduced oxygen affinity (a shift to the right of the oxygen dissociation curve). The conformational change induced by binding of oxygen alters the binding site for 2,3-BPG and results in release of 2,3-BPG from hemoglobin. This facilitates uptake of more oxygen for delivery to tissues. The concentration of 2,3-BPG increases whenever there is tissue hypoxemia but may decrease in the presence of acidosis or hypophosphatemia. Thus, hypophosphatemia may result in a left shift of the oxygen dissociation curve.

Clofibrate and bezafibrate (lipid lowering drugs used to treat hyperlipidemia) are capable of lowering the oxygen affinity of hemoglobin, analogous to 2,3-BPG (Poyart et al., 1994). However, the association constant of bezafibrate for hemoglobin is too low for there to be a meaningful effect in vivo.

The oxygen affinity of hemoglobin decreases as the body temperature increases (Hsia, 1998). This facilitates delivery of oxygen to tissues during periods of extreme exercise and febrile illnesses associated with increased temperature. Correspondingly, oxygen affinity increases during hypothermia, which may lead to decreased oxygen delivery under these conditions. This must be taken into consideration during surgical procedures during which there is induction of deep hypothermia.

Carboxyhemoglobinemia The respiratory function of hemoglobin may also be impaired by blockade of the ligand binding site following interaction with other substances, most notably carbon monoxide (CO) (Hsia, 1998). CO has a relatively low rate of association with deoxyhemoglobin but has high affinity once bound. The affinity is about 200 times that of oxygen, and thus persistent exposure to a low level of CO (e.g., 0.1%) may lead to 50% saturation of hemoglobin. Binding of carbon monoxide also results in stabilization of the hemoglobin molecule in the high-affinity "R" conformation. Consequently, the oxygen dissociation curve is shifted to the left, further compromising oxygen delivery to the tissues. Low amounts of CO are produced at low levels by the body through the metabolism of heme and equilibrate across the pulmonary capillary/alveolar bed. At these low levels, CO is necessary for cell signaling and function and holds therapeutic potential (Fix et al., 2015).

The major sources of significant exogenous exposure to CO are smoking and burning of fossil fuels (including automobiles), particularly in enclosed spaces. Smoking tobacco or marijuana elevates levels of carboxyhemoglobin in the blood turning it bright cherry red. Smoking during pregnancy may also result in significant levels of carboxyhemoglobin being formed in fetal blood and diminished oxygenation of fetal tissues. At levels below 10% carboxyhemoglobin (resulting from 35 ppm exposure), headache and dizziness may occur after 6 to 8 hours of constant exposure (Struttmann et al., 1998). Other symptoms of toxicity, such as weakness, dizziness, shortness of breath, headache, nausea, and blurred vision begin to appear within a few hours when carboxyhemoglobin levels reach 20%. Patients may have a bluish-tinted skin. Levels of 50% to 80% carboxyhemoglobin may be lethal. Diagnosis of acute CO poisoning can be challenging if there is a delay of a few hours between exposure and blood sampling due to the short half-life of carboxyhemoglobin and carboxyhemoglobin levels may differ among individuals exposed to the same levels of carbon monoxide. This means that there can be a relatively poor correlation between carboxyhemoglobin levels and the symptoms of CO poisoning. The key to therapy is removal from the source of CO and provision of an adequate supply of oxygen; hyperbaric hyperoxia may be used in serious cases (Ryter and Otterbein, 2004; Kao and Nanagas, 2005). It is now known that CO has additional effects other than carboxyhemoglobin formation, including roles in nitric oxide release and reactive oxygen species formation (Roderique et al., 2015). CO also interacts with other heme-containing proteins including myoglobin and cytochromes. Relapses in persons recovering from acute CO poisoning are most likely due to CO storage in myoglobin (Dolan, 1985). Adjunct and combination therapeutic approaches are under consideration to counteract some of these other mechanisms of toxicity.

Sulfhemoglobin and Hydrogen Sulfide Poisoning Sulfhemoglobin is a greenish pigment formed when hydrogen sulfide gas is bubbled through blood, but it plays no role in acute hydrogen sulfide poisoning. It has, however, been observed in patients exposed to high doses of the azo-dye phenazopyridine (Gopalachar et al., 2005) and the sulfonamide drug sumatriptan (Flexman et al., 2007). In the latter case report, the blood of the patient overdosed with sumatriptan was green in color. Methemoglobin also forms a complex with hydrosulfide ion, known as sulfmethemoglobin, which is analogous to cyanmethemoglobin formed after exposure to cyanide. Hydrogen sulfide poisoning is almost identical to cyanide poisoning, but sulfide also produces local tissue reactions such as conjunctivitis and pulmonary edema (Guidotti, 2015). As with cyanide-poisoning, nitrite-induced methemoglobinemia is used to treat hydrogen sulfide poisoning and provides considerable protection and antidotal effects in animals and humans. Acute poisoning with hydrogen sulfide is primarily a hazard in the oil and gas industry, agriculture, sewage and animal waste handling, construction (asphalt operations and disturbing marshy terrain), and other settings where organic material decomposes under reducing conditions (producing sewer gas), as well as in geothermal operations (Guidotti, 2015).

Alterations in Erythrocyte Survival

The normal survival of erythrocytes in the circulation is about 120 days (Dessypris, 1999). During this period the erythrocytes are exposed to a variety of oxidative injuries and must negotiate the tortuous passages of the microcirculation and the spleen. This requires a deformable cell membrane and energy to maintain the sodium–potassium gradients and repair mechanisms (Van Wijk and van Solinge, 2005). Very little protein synthesis occurs during this time, as erythrocytes are anucleate when they enter the circulation and residual mRNA is rapidly lost over the first 1 to 2 days in the circulation. Consequently, senescence occurs over time until the aged erythrocytes are removed by the spleen, where the iron is recovered for reutilization in heme synthesis. Any insult

that increases oxidative injury, decreases metabolism, or alters the membrane may cause a decrease in erythrocyte concentration and a corresponding anemia.

Nonimmune Hemolytic Anemia

Microangiopathic Anemias Intravascular fragmentation of erythrocytes gives rise to *microangiopathic hemolytic anemia* (Baker, 2006). The hallmark of this process is the presence of schistocytes (fragmented RBCs) in the peripheral blood. These abnormal cellular fragments are usually promptly cleared from the circulation by the spleen. Thus, their presence in peripheral blood samples indicates either an increased rate of formation or abnormal clearance function of the spleen. The formation of fibrin strands in the microcirculation is a common mechanism for RBC fragmentation. This may occur in the setting of disseminated intravascular coagulation, sepsis, the hemolytic-uremic syndrome (HUS), and thrombotic thrombocytopenic purpura (TTP). The erythrocytes are essentially sliced into fragments by the fibrin strands that extend across the vascular lumen and impede the flow of erythrocytes through the vasculature. Excessive fragmentation can also be seen in the presence of abnormal vasculature, as occurs with damaged cardiac valves, arteriovenous malformations, vasculitis, and widely metastatic carcinoma (Baker, 2006). The high shear associated with malignant hypertension may also lead to RBC fragmentation. Around 170 cases of cancer-related microangiopathic hemolytic anemia cases were reported in the literature as reviewed (Lechner and Obermeier, 2012), the majority associated with metastatic solid cancers and a minority with lymphoma. Cocaine use has been associated with microangiopathic hemolytic anemia, possibly via cocaine-induced vasoconstriction, vascular damage, platelet activation, and procoagulation (Odronic et al., 2014).

Oxidative Hemolysis Molecular oxygen is a reactive and potentially toxic chemical species; consequently, the normal respiratory function of erythrocytes generates oxidative stress on a continuous basis. The major mechanisms that protect against oxidative injury in erythrocytes include NADH-methemoglobin reductase, superoxide dismutase, catalase, and the glutathione pathway (Coleman and Coleman, 1996; Njalsson and Norgren, 2005). As indicated previously, a small amount of methemoglobin is continuously formed during the process of loading and unloading of oxygen from hemoglobin. Formation of methemoglobin is associated with formation of superoxide free radicals, which must be detoxified to prevent oxidative injury to hemoglobin and other critical erythrocyte components. Under physiologic conditions, superoxide dismutase converts superoxide into hydrogen peroxide, which is then metabolized by catalase and glutathione peroxidase (Fig. 11-6).

A number of xenobiotics, particularly compounds containing aromatic amines, are capable of inducing oxidative injury in erythrocytes (Table 11-6) (Bradberry, 2003; Percy et al., 2005). These chemicals appear to potentiate the normal redox reactions and are capable of overwhelming the usual protective mechanisms. The interaction between these xenobiotics and hemoglobin leads to the formation of free radicals that denature critical proteins, including hemoglobin, thiol-dependent enzymes, and components of the erythrocyte membrane. In the presence of hydrogen peroxide and xenobiotics such as hydroxylamine, hydroxamic acid, and phenolic compounds, a reactive ferryl (Fe^{4+}) hemoglobin intermediate may be formed according to the following reaction:

$$H_2O_2 + Hgb - Fe^{3+} \rightarrow H_2O + Hgb(\bullet +) - Fe^{4+} - O^{-}.$$

In this intermediate, referred to as compound 1, tyrosine may donate the extra electron, turning it into a reactive free radical. Compound 1 may undergo further reaction with organic compounds

Table 11-6

Xenobiotics Associated with Oxidative Injury

Arsine	Copper
Acetanilide	Phenylhydrazine
Naphthalene	Nitrobenzene
Nitrofurantoin	Phenacetin
Sulfamethoxypyridazine	Phenol
Aminosalicylic acid	Hydroxylamine
Sodium sulfoxone	Methylene blue
Dapsone	Toluidine blue
Phenazopyridine	Furazolidone
Primaquine	Nalidixic acid
Chlorates	Sulfanilamide
Sulfasalazine	

(AH_2 in the following equations) to yield additional free radicals according to the following reactions:

$$Hgb(\bullet +) - Fe^{4+} - O + AH_2 \rightarrow Hgb - Fe^{4+} - O^{-} + AH\bullet + H^{+};$$
$$Hgb - Fe^{4+} - O^{-} + AH_2 + H^{+} \rightarrow Hgb - Fe^{3+} + AH\bullet + H_2O.$$

Hemoglobin contains free exposed cysteines (β93) that are critical for the structural integrity of the molecule. Oxidation of these groups can denature hemoglobin and decrease its solubility. The oxidized, denatured hemoglobin species comprise what has been designated sulfhemoglobin. The denatured hemoglobin can form aggregates that bind to the cell membrane to form inclusions called *Heinz bodies,* a hallmark of oxidative injury to erythrocytes (Jandl, 1987). Heinz bodies are usually visualized by use of phase contrast microscopy or supravital stains such as crystal violet or more recently by flow cytometry (Palasuwan et al., 2017). These membrane-associated inclusions impair the deformability of the erythrocyte membrane and thus impede movement of erythrocytes through the microcirculation and the spleen. Heinz bodies are effectively removed from the erythrocyte by the spleen, so they are not often observed in peripheral blood samples from patients despite ongoing oxidative injury. However, the culling of Heinz bodies can alter the morphology of the affected cells, giving rise to what are called "bite" cells and "blister" cells, which may provide an important clue as to the ongoing process (Yoo and Lessin, 1992). These cells look as though a portion of the cytoplasm had been cut away. Heinz body formation can be induced by in vitro exposure to oxidizing agents and patients with oxidative hemolysis often show increased in vitro formation of Heinz bodies.

Oxidative denaturation of the globin chain decreases its affinity for the heme group, which may dissociate from the globin chain during oxidative injury (Kumar and Bandyopadhyay, 2005). Free heme itself is toxic to cells and can induce tissue injury through formation of reactive oxygen species. The ferric iron in the heme ring may react with chloride to form a complex called hemin. Hemin is hydrophobic and intercalates into the erythrocyte membrane from which it is removed by interaction with albumin. However, if the rate of hemin formation exceeds the rate of removal by albumin, hemin accumulates in the membrane, where it can cause rapid lysis of the erythrocyte.

The generation of free radicals may also lead to peroxidation of membrane lipids (Jandl, 1987; Kumar and Bandyopadhyay, 2005). This may affect the deformability of the erythrocyte and the permeability of the membrane to potassium. The alteration of the Na^+/K^+ gradient is independent of injury to the Na^+/K^+ pump and is potentially lethal to the affected erythrocyte. Oxidative injury also

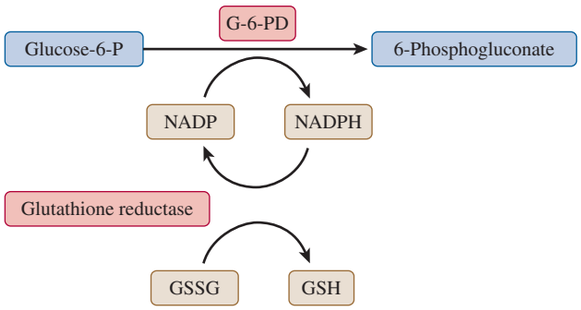

Figure 11-7. *The hexose monophosphate shunt in the erythrocyte is critical for generation of NADPH, which helps maintain an intracellular supply of reduced glutathione (GSH).* With a deficiency of glucose-6-phosphate dehydrogenase (G-6-PD), the rate-limiting step in this pathway, the cellular levels of GSH are reduced. Such cells show increased susceptibility to oxidative injury. Acute exposure of such cells to an oxidizing agent can result in rapid hemolysis.

impairs the metabolic machinery of the erythrocyte, resulting in a decrease in the concentration of ATP (Tavazzi et al., 2000). Damage to the membrane can also permit leakage of denatured hemoglobin from the cell. Such free denatured hemoglobin can be toxic on its own. Free hemoglobin may irreversibly bind nitric oxide, resulting in vasoconstriction. Released hemoglobin may form nephrotoxic hemoglobin dimers, leading to kidney damage.

Oxidative injury thus results in a number of changes that decrease the viability of erythrocytes. Protection against many of the free radical–induced modifications is mediated by reduced glutathione, along with antioxidant defense enzymes including superoxide dismutase, catalase, and glutathione peroxidase, and glutathione reductase (Njalsson and Norgren, 2005; Perrone et al., 2012) (see Chap. 3). Formation of reduced glutathione is dependent on NADPH and the hexose monophosphate shunt (Fig. 11-7). Significant oxidative injury usually occurs when the concentration of the xenobiotic is high enough (due to either high exposure or decreased metabolism of the xenobiotic) to overcome the normal protective mechanisms, or, more commonly, when there is an underlying defect in the protective mechanisms.

The most common enzyme defect associated with oxidative hemolysis is G-6-PD deficiency, a relatively common X-linked disorder characterized by alterations in the primary structure of G-6-PD that diminish its functional activity (Beutler, 1996). It is often clinically asymptomatic until the erythrocytes are exposed to oxidative stress. The stress may come from the host response to infection or exposure to xenobiotics. The level of G-6-PD normally decreases as the erythrocytes age. Over 140 mutations have been identified (Mason et al., 2007; Cappellini and Fiorelli, 2008) and high-frequency variants are found in African, Mediterranean, and Asiatic populations (Porter et al., 1964). G-6-PD deficiency may have developed as a protection against malaria, which is endemic in these regions (Luzzatto et al., 1969). In the African type of G-6-PD deficiency, the enzyme is less stable than normal; thus, the loss of activity is accelerated compared with normals. In the Mediterranean type of G-6-PD deficiency, the rate of loss of enzyme activity is even higher. Consequently, the older erythrocytes with the lowest levels of G-6-PD are most susceptible to hemolysis, with the degree of hemolysis affected by the residual amount of enzyme activity as well as the magnitude of the oxidative injury.

Erythrocyte-reduced glutathione is rapidly depleted on exposure to an oxidizing chemical in patients with G-6-PD deficiency. This leads to the series of oxidative injuries described above with the development of intravascular and extravascular hemolysis. Oxidative hemolysis is usually reversible if the process is promptly recognized and the offending chemical is removed. Occasionally the hemolysis may be sufficiently severe to result in death or serious morbidity (e.g., renal failure). A connection between fava bean ingestion and hemolytic anemia was recognized around 510 BC, by the philosopher and mathematician Pythagoras who forbade his followers from eating the *Vicia faba*. The link was later confirmed and called favism and recognized as being associated with G-6-PD deficiency (Mason et al., 2007; Ho et al., 2014). Following fava bean ingestion, the generation of divicine and isouramil, from vicine and convicine, leads to peroxide production and GSH oxidation and depletion (Winterbourn, 1989; Winterbourn et al., 1989). The resulting anemia is acute and severe. In a similar manner to fava beans, the malaria drug primaquine causes hemolysis in G-6-PD-deficient individuals (Alving et al., 1956; Beutler, 1996; Howes et al., 2013; Watson et al., 2017). Copper toxicity also causes hemolysis and methemoglobinemia in G-6-PD deficient individuals (Moore and Calabrese, 1980; Yang et al., 2004). Copper generates free radicals and inhibits enzymes of erythrocyte metabolism including NADPH-methemoglobin reductase (Clopton and Saltman, 1997).

Deficiency of glutathione synthetase can also lead to hemolytic anemia due to the reduced intracellular concentration of glutathione (Njalsson and Norgren, 2005; Ristoff and Larsson, 2007; Soylu Ustkoyuncu et al., 2017).

Nonoxidative Chemical-Induced Hemolysis Some xenobiotics act by both oxidative and nonoxidative mechanisms while some are associated with hemolysis without significant oxidative injury (Beutler, 2006a, 2006b, 2006c). Arsenic hydride is a gas that is formed during several industrial processes. Inhalation of the gas can result in severe hemolysis, with anemia, jaundice, and hemoglobinuria. Arsine has oxidative effects and also possibly acts on the Na^+/K^+ pump mechanism, leading to swelling and hemolysis (Pakulska and Czerczak, 2006). Stibine, a colorless gas and principal covalent hydride of antimony that is used to dope silicon with antimony in the semiconductor industry, causes severe hemolysis but the mechanism is unknown. Lead poisoning is associated with defects in heme synthesis and a shortening of erythrocyte survival. The cause of the hemolysis is uncertain, but lead can cause membrane damage and interfere with the Na^+/K^+ pump (Suwalsky et al., 2003; Rehman, 2013). These effects may cause premature removal of erythrocytes from the circulation. Excess copper has oxidative effects as mentioned above and also exerts inhibitory effects on the hexose monophosphate shunt and the Embden–Meyerhof pathway. Ingestion of excess chromium may result in hemolytic anemia and thrombocytopenia, although the mechanism is not known (Cerulli et al., 1998; Ray and Sarkar, 2012). However, hexavalent chromium also leads to eryptosis—apoptosis-like cell death—through increased Ca^{2+} entry and depleted cytosolic ATP in erythrocytes, rather than hemolysis (Lupescu et al., 2012). Significant hemolysis may also occur with biologic toxins found in insect and snake venoms, through unknown mechanisms (Beutler, 2006a, 2006b, 2006c).

Immune Hemolytic Anemia Immunologic destruction of erythrocytes is mediated by the interaction of IgG or IgM antibodies with antigens expressed on the surface of the erythrocyte. In the case of autoimmune hemolytic anemia the antigens are intrinsic components of the patient's own erythrocytes. A large number of drugs have been associated with enhanced binding of immunoglobulin to the erythrocyte surface and shortened RBC survival (Arndt and Garratty, 2005).

A number of mechanisms have been implicated in xenobiotic-mediated antibody binding to erythrocytes (Arndt and Garratty,

2005). Some drugs, of which penicillin is a prototype, appear to bind to the surface of the cell, with the "foreign" drug acting as a *hapten* and eliciting an immune response. The antibodies that arise in this type of response only bind to drug-coated erythrocytes. Other drugs, of which quinidine is a prototype, bind to components of the erythrocyte surface and induce a conformational change in one or more components of the membrane. This type of interaction can give rise to a confusing array of antibody specificities. Some of the antibodies recognize only the *drug–membrane component* complex; others are specific for the membrane component, but only when drug is present; while still others may recognize the membrane component in the presence or absence of the drug. An additional mechanism, for which α-methyldopa is a prototype, results in production of a *drug-induced autoantibody* that cannot be distinguished from the antibodies arising in idiopathic autoimmune hemolytic anemia. The mechanism for induction of this group of antibodies is not understood, but may be related to development of an autoimmune response. A variant of this type of response is the augmentation of autoimmune hemolytic anemia that may occur during therapy of some lymphoproliferative disorders. Autoimmune phenomena, including autoimmune hemolytic anemia, are known to occur in lymphoproliferative disorders such as chronic lymphocytic leukemia (CLL). Treatment of these disorders with some drugs has been associated with worsening of the hemolytic anemia (Gonzalez et al., 1998). It has been hypothesized that therapy further disrupts regulation of the autoimmune phenomenon, allowing increased antibody production.

Some xenobiotics are associated with *nonspecific deposition of proteins* on erythrocytes. This was first associated with cephalosporins (beta-lactam antibacterials) but has also been seen with other drugs, including cisplatin (antineoplastic) and the beta-lactam antibacterials sulbactam and clavulanate (Arndt and Garratty, 2005). Immunoglobulin and complement proteins may be among the proteins deposited on the erythrocyte surface. These proteins may cause a positive direct antiglobulin test, suggesting a drug-induced antibody response. However, there is no evidence of a drug-dependent antibody in the patient's serum, and drug-treated erythrocytes may bind antibody from normal nondrug exposed serum. This form of antibody deposition is generally not associated with hemolysis, although the possibility of hemolysis related to this type of reaction has been raised.

Drug-induced intravascular hemolysis is often a dramatic clinical event and may be associated with fever, chills, back pain, hypotension, a rapid fall in hemoglobin concentration, a decrease in serum haptoglobin, a marked increase in serum lactate dehydrogenase, and hemoglobinuria (Arndt and Garratty, 2005). The clinical picture of extravascular hemolysis depends on the rate of hemolysis but is usually less dramatic. Often there is evidence of reticulocytosis, polychromasia, spherocytosis, a moderate increase in serum lactate dehydrogenase, and an increase in serum bilirubin. Serologic studies usually show evidence of IgG and/or complement on the surface of erythrocytes, although it may be difficult to document that antibody binding is drug-dependent. The mainstay of therapy in patients with drug-induced hemolytic anemia is removal of the offending agent and avoidance of reexposure.

TOXICOLOGY OF THE LEUKON

Components of Blood Leukocytes

The leukon consists of leukocytes, or white blood cells. They include granulocytes, which may be subdivided into neutrophils, eosinophils, and basophils; monocytes; and lymphocytes. Granulocytes and monocytes are nucleated ameboid cells that are phagocytic. They play a central role in the inflammatory response and host defense. Unlike the RBCs, which reside exclusively within blood, granulocytes and monocytes generally pass through the blood on their way to the extravascular tissues, where they reside in large numbers. Circulating mature neutrophils undergo senescence, and the consequent increased membrane expression of CXCR4 leads them to migrate to different tissues in response to the chemokine CXCL12 (Martin et al., 2003; Eash et al., 2009). In mice, around a third of senescent neutrophils home to the bone marrow via CXCL12/CXCR4 chemotaxis, and undergo apoptosis and phagocytosis by macrophages (Furze and Rankin, 2008a, 2008b). The engulfing macrophages produce G-CSF thus stimulating neutrophil production (Furze and Rankin, 2008a, 2008b; Summers et al., 2010). The glucocorticoid-regulated protein, annexin A1, was recently shown to modulate neutrophil maturation and senescent neutrophil homing to the bone marrow (Dalli et al., 2012; Machado et al., 2014; Machado et al., 2016).

Granulocytes are defined by the characteristics of their cytoplasmic granules as they appear on a blood smear stained with a polychromatic (Romanovsky) stain. Neutrophils, the largest component of blood leukocytes, are highly specialized in the mediation of inflammation and the ingestion and destruction of pathogenic microorganisms. The turnover of neutrophils is enormous and increases dramatically in times of inflammation and infection, elevating the number of these cells released from the bone marrow. Eosinophils and basophils modulate inflammation through the release of various mediators and play an important role in other homeostatic functions. All these are influenced by cellular and humoral immune responses.

In the world of clinical and experimental toxicology, the neutrophil is the focus of concern when evaluating granulocytes as possible targets for drug and nontherapeutic chemical effects. Eosinophils and basophils are far more difficult to study, with changes in these populations most frequently associated with reactions to other target organs or systemic toxicity. Examples include the eosinophilia observed with the toxic oil syndrome that resulted from exposure to rapeseed oil denatured with aniline utilized in northwestern Spain (Kilbourne et al., 1991), and the eosinophilia–myalgia syndrome associated with λ-tryptophan preparations contaminated with 1,1-ethylidene-bis[tryptophan] (Varga et al., 1992). Peripheral eosinophilia is often but not reliably observed with hypersensitivity reactions to drugs (Roujeau, 2005), while tissue eosinophilia can be diagnostic, in the context of a suggestive clinical course, in conditions such as drug-induced cutaneous vasculitis (Bahrami et al., 2006) and eosinophilic pneumonia (Flieder and Travis, 2004). This variability in systemic response can be genetically predisposed, as demonstrated in studies using transgenic mice on genetic restrictions in people afflicted by the aforementioned toxic oil syndrome (Gallardo et al., 2005). The time course of the reaction can also influence whether eosinophilia can be demonstrated in hypersensitivity disease (Roujeau, 2005).

Evaluation of Granulocytes

The most informative test to assess the neutrophil compartment is the blood neutrophil count. Accurate interpretation requires an understanding of neutrophil kinetics and the response of this tissue to physiologic and pathologic changes. In the blood, neutrophils are distributed between *circulating* and *marginated* pools, which are of equal size in humans and in constant equilibrium (Athens et al., 1961). A blood neutrophil count assesses only the circulating pool, which remains between 1800/μL and 7500/μL in a healthy adult human (Dale, 2006).

This constancy is remarkable, considering that as many as 10^{11} neutrophils are released from the marrow daily, that this circulating pool represents only 1% of the total body neutrophils (Semerad et al., 2002), and that the circulating half-life of these cells is only approximately 6 hours (Cartwright et al., 1964). How this extraordinary regulation is achieved is not fully understood. The upregulation and downregulation of chemokine receptors is involved in the release of neutrophils from the bone marrow and their return following senescence (Martin et al., 2003). IL-23, IL-17, and G-CSF modulate niche size, with consequent effects on hematopoietic stem/progenitor cells and their fates. An expanded view of the regulation of neutrophil homeostasis has been developed recently and involves a role for the innate immune system in sensing and regulating granulopoiesis and a dependence on danger receptors, macrophages, and circadian rhythms (Schuettpelz et al., 2014; Wirths et al., 2014).

Neutrophil kinetics and response to disease vary substantially among animal species (Feldman et al., 2006). Thus, a thorough understanding of these features in any animal model used in investigative toxicology is required before informed interpretations can be made. In humans, clinically significant neutropenia occurs when the blood neutrophil count is less than 1000/μL, but serious recurrent infections do not usually occur until counts fall below 500/μL (Dale, 2006). Morphologic assessment of peripheral blood granulocytes can be helpful in characterizing neutropenia. In humans and most healthy animal species, mature (segmented) and a few immature (band) neutrophils can be identified on blood films stained with Wright or Giemsa stain. During inflammation, a "shift to the left" may occur, which refers to an increased number of immature (nonsegmented) granulocytes in the peripheral blood, which may include bands, metamyelocytes, and occasionally myelocytes. During such times, neutrophils may also show "toxic" granulation, Döhle bodies, and cytoplasmic vacuoles. These morphologic changes may be prominent in sepsis or as a result of drug or chemical intoxication. In order to fully characterize such changes or understand the pathogenesis of the abnormality, bone marrow must be examined using marrow aspirates and biopsies. These provide information on rates of production, bone marrow reserves, and abnormalities in cell distribution, and occasionally specific clues as to etiology. In vitro stem cell assays may be used to assess the granulocyte progenitor cell compartment, which may include colony-forming-units granulocyte/monocyte (CFU-GM) performed in a semisolid medium, such as agar or methylcellulose, which contains appropriate growth factors, as discussed later in this chapter. Normal human marrow specimens contain approximately 50 to 1000 CFU-GM per 10^6 nucleated cells cultured (Liesveld and Lichtman, 1997). Marrow stem cell reserves can be assessed in vitro after administration of G-CSF (Demirer and Bensinger, 1995), which stimulates increased production and release of neutrophil precursors. Glucocorticoids (Peters et al., 1972) and epinephrine (Babior and Golde, 1995) may also be used for this purpose but are rarely used in a clinical setting.

CXCL12, the CXC chemokine ligand of CXCR4, mediates the retention of myeloid stem cells within their bone marrow niche (Laurence, 2006; Sharma et al., 2011), as well as mature neutrophils within the bone marrow pool (Semerad et al., 2002). Plerixafor is an inhibitor of CXCR4 that, when administered with G-CSF, can cause a transient release of neutrophils and CD34+ (stem) cells into the circulation (Liles et al., 2005). The latter can be collected and re-engrafted to form new functioning bone marrow (Broxmeyer et al., 2005). Plerixafor is approved for mobilization in combination with G-CSF in patients with non-Hodgkin lymphoma and multiple myeloma (Pusic and DiPersio, 2010) and works even in very poor mobilizers (Mohty et al., 2017). Several newer classes of CXCR4 antagonists are in development (Domingues et al., 2017b). The homing and retention of such hematopoietic stem/progenitor cells is influenced by complex and highly coordinated interactions among adhesion molecules, cytokines, growth factors, and regulatory cofactors that are only partially understood (Sharma et al., 2011). The ability to manipulate this system, as in the above experiments and through the many recombinant proteins under development, will continue to provide important research, diagnostic, and therapeutic tools for the hematologist, oncologist, and toxicologist.

The degree of proliferation in the granulocyte compartment can also be assessed using older techniques that employ ^{3}H-thymidine suicide assays or DNA-binding dyes with fluorescence-activated cell sorting analyses (Keng, 1986). In recent years, neutrophils have been found to more plastic and heterogeneous than previously thought (Kruger et al., 2015; Scapini et al., 2016; Marini et al., 2017). CD10 was identified as a novel surface marker with the potential to distinguish T-cell suppressive and T-cell stimulatory neutrophils in peripheral blood (Kruger et al., 2015).

Toxic Effects on Granulocytes

The toxicologist is concerned with the effect of xenobiotics on granulocytes as relates to proliferation (granulopoiesis) and kinetics, the extent to which a drug or chemical contaminant can impair the vital functions these cells perform, and how neutrophils mediate or exacerbate inflammatory disease or other target organ toxicity. The last two areas are discussed in Chap. 12, as they relate to their role as important effector cells of the immune system. However, it is difficult to separate effects on granulopoiesis and neutrophil kinetics from that of function. Both are complex and highly regulated, as discussed above, through an array of growth factors, chemokines, cytokines, and interactions with monocytes, dendritic cells, and lymphocytes in a bidirectional, multicompartmental manner (Nathan, 2006). Such complexity is not surprising, given the daunting task these cells perform, which is elegantly described in a review by Nathan (2006): "The [neutrophil] must remain non-sticky as it hurtles through the arterial and arteriolar circulation; then it must squeeze through capillaries smaller in diameter than itself, without allowing collision, friction, or distortion to activate it. A fraction of the population must adhere tightly enough to the normal endothelium of post-capillary venules to resist being washed away in the circulation, but loosely enough to roll while scouting for evidence of tissue damage and microbial infection. If such evidence is received, the cell must crawl to a boundary between endothelial cells, penetrate the junctions and the underlying basement membrane without damaging these structures, move up the chemotactic gradient, and decide whether its original information remains valid. If the answer is negative, the cell must execute itself by apoptosis. If the answer is positive, the cell must attempt to engulf and destroy microbes. If it cannot locate microbes quickly, it must attempt to destroy them at a distance by releasing every weapon at its disposal." Many of the mediators and interactions that enable this feat have now become targets for the therapeutic dysregulation of these processes, which has led to the development of candidate drugs that may prove to be uniquely efficacious and/or toxic, as discussed below.

Effects on Proliferation and Kinetics

As with other hematopoietic tissue, the high rate of proliferation of neutrophils makes their progenitor and precursor granulocyte pool particularly susceptible to inhibitors of mitosis. Such effects by cytotoxic drugs are generally nonspecific, as they similarly affect cells of the dermis, gastrointestinal tract, and other rapidly dividing tissues. Agents that affect both neutrophils and monocytes pose a greater risk for toxic sequelae, such as infection (Dale, 2006). Such effects tend to be

dose-related, with mononuclear phagocyte recovery preceding neutrophil recovery (Arneborn and Palmblad, 1982).

Myelotoxicity in clinical medicine and preclinical safety studies today is most commonly seen with cytoreductive cancer chemotherapy drugs. However, this is changing, as more cancer cell–targeted, normal-tissue-sparing anticancer agents are being developed. In fact, most published reviews today on drug-induced neutropenia and agranulocytosis do not even address these effects associated with such cytotoxic drugs. Accordingly, the term commonly refers to *idiosyncratic reactions,* most often secondary to accelerated immune-mediated destruction of neutrophils and their progenitors, as discussed below. The toxicity associated with cytotoxic drugs, however, remains important in that it is often dose-limiting with serious manifestations that include febrile neutropenia associated with life-threatening infections (Kuderer et al., 2002). These drugs vary in terms of their mechanism, the kinetics of the cytopenias they induce, and how individual patients or animals respond. Most act to inhibit DNA synthesis or directly attack its integrity through the formation of DNA adducts or enzyme-mediated breaks (Chabner et al., 2006). While cytoreductive drugs such as alkylating agents, cisplatin, and nitrosoureas can be toxic to both resting and actively dividing cells, nonproliferating cells such as metamyelocytes, bands, and mature neutrophils are relatively resistant (Friberg and Karlsson, 2003). Generally, stem cells cycle slowly and are therefore minimally affected by a single administration of a cytotoxic drug such as 5-fluorouricil; however, such exposure can stimulate cycling activity, making these cells more vulnerable to doses administered 3 to 5 days later (Harrison and Lerner, 1991). Sustained exposure to drugs affecting slowly cycling stem cells is thought to cause more prolonged myelosuppression, similar to that observed with idiosyncratic toxic neutropenia (Tannock, 1986). Recent studies suggest that these features are shared by leukemic stem cells, which is the basis for the more sophisticated cancer interventions and regimens under development today (Eramo et al., 2008; Ricci-Vitiani et al., 2010; Vermeulen et al., 2010).

Finally, there is considerable variation among individuals as regards susceptibility to bone marrow toxicity, related to drug metabolism as with 5-fluorouracil (Sundman-Engberg et al., 1998) and 6-mercaptopurine (Chabner et al., 2006), gender (Huang et al., 2007; Gamazon et al., 2011), and other factors. Based on these and other data, including plasma drug concentrations, "semi-mechanistic" pharmacokinetic/pharmacodynamic models of myelosuppression have been developed to tailor doses and treatment regimens to individual patients (Friberg and Karlsson, 2003). Pharmacokinetic monitoring is now routinely performed with some anticancer treatment regimens, particularly high-dose methotrexate (Chabner et al., 2006).

Two innovations have had a dramatic impact on cancer chemotherapy and the dose-limiting myelotoxicity associated with these drugs: (1) the aforementioned development of drugs with cancer cell–specific molecular targets that are relatively bone marrow sparing, such as those that target aberrant growth factor receptor signaling, apoptosis, angiogenesis, and other metabolic, immune, inflammatory, and mutation-promoting pathways that selectively advantage tumor cells (Hanahan and Weinberg, 2011); and (2) the use of hematopoietic growth factors, the cotreatment with which mitigates or successfully rescues patients from the effects of myelosuppression (Andres et al., 2010).

Lindane, an insecticide used to treat seeds and soil, has been associated with leukopenia (Parent-Massin et al., 1994). It is cytotoxic for human CFU-GMs at concentrations observed in blood and adipose tissue from exposed human subjects. An example of chemicals affecting mature cells is methyl methacrylate monomer, which has been used in orthopedic surgical procedures and is cytotoxic to both neutrophils and monocytes at clinically relevant concentrations (Dahl et al., 1994).

Chemicals that affect granulocyte kinetics can cause neutropenia or neutrophilia that has variable toxicologic significance. The effects of epinephrine and glucocorticoids on granulocyte kinetics were discussed previously. Dexamethasone has long been known to cause neutrophilia through enhanced release of mature neutrophils from the bone marrow and demargination (release of neutrophils from the endovascular lining of the blood vessel into circulation), with the latter being the largest contributor to the expanded circulating pool (Nakagawa et al., 1998). It is now clear that the reduced margination of neutrophils is mediated by multiple effects, including altered chemotaxis, expression of adhesion molecules, and the release of mediators from other cells (Caramori and Adcock, 2005; Barnes, 2006). It is widely assumed that inhibition of margination and homing (migration to the organ of origin, i.e., bone marrow) are among the important mechanisms of the anti-inflammatory and immunosuppressive effects of these widely used drugs.

Effects on Function While there are a variety of disorders associated with defects in the parameters of neutrophil function discussed above, demonstrable in vivo effects associated with drugs and nontherapeutic chemicals are surprisingly few (Borregaard and Boxer, 2006). Examples include ethanol and glucocorticoids, which impair phagocytosis and microbe ingestion in vitro and in vivo (Brayton et al., 1970). Iohexol and ioxaglate, components of radiographic contrast media, have also been reported to inhibit phagocytosis (Lillevang et al., 1994). Superoxide production, required for microbial killing and chemotaxis, has been reported to be reduced in patients using parenteral heroin as well as in former opiate abusers on long-term methadone maintenance (Mazzone et al., 1994).

In addition to glucocorticoids, several drugs and nontherapeutic chemicals have been shown to inhibit neutrophil chemotaxis. Examples include macrolide antibiotics, which suppress the expression of the adhesion molecule ICAM (Tamaoki, 2004); zinc salts, which are found in antiacne preparations (Dreno et al., 1992); the insecticide chlordane (Miyagi et al., 1998); and mercuric chloride/methylmercuric chloride (Contrino et al., 1988). More common is the activation of neutrophils with the potential for proinflammatory consequences, specifically through increased phagocytosis, O_2^- production, or both. Examples include the environmental contaminants sodium sulfite, mercuric chloride, chlordane, and toxaphene (Girard, 2003).

Idiosyncratic Toxic Neutropenia Of greater concern are chemicals that unexpectedly damage neutrophils and granulocyte precursors—particularly to the extent of inducing *agranulocytosis,* which is characterized by a profound depletion in blood neutrophils to less than 500/μL (Pisciotta, 1973). The term was first used by Schultz in 1922 to describe patients with severe sore throat associated with a marked reduction of granulocytes, followed by sepsis and death (Schultz, 1922). Drug association was first demonstrated through rechallenge experiments performed on two patients with aminopyrine-induced agranulocytosis, who developed leucopenia within 2 hours of reexposure (Madison and Squier, 1934). A later study demonstrated that blood transferred from an agranulocytosis patient to normal controls resulted in a rapid drop in neutrophil count, suggesting a role for a preformed blood factor(s) such as antibodies (Moeschlin and Wagner, 1952). Such toxicity occurs in specifically conditioned individuals, and is therefore termed "idiosyncratic." While rare, the seriousness of this disorder, as with aplastic anemia, makes it among the most important hematotoxicities, as

Table 11-7

Stages of Granulocytopoiesis: Site of Xenobiotic-Induced Cellular Damage

STAGE OF DEVELOPMENT	DISEASE	OFFENDING DRUGS
Uncommitted (totipotential) stem cell CFU-S	Aplastic anemia	Chloramphenicol Gold salts Phenylbutazone Phenytoin Mephenytoin Carbamazepine
Committed stem cell CFU-G CFU-E BFU-E	Aplastic anemia Agranulocytosis Pure red cell aplasia	Carbamazepine Chlorpromazine Carbamazepine Clozapine Phenytoin
Morphologically recognizable precursors	Hypoplastic marrow	Most cancer chemotherapy agents
Dividing pool Promyelocyte Myelocyte	Hypoplastic marrow	Chloramphenicol Alcohol
Nondividing pool Metamyelocytes, bands PMNs	Agranulocytosis	Clozapine Phenothiazines, etc.
Peripheral blood lysis PMNs	Agranulocytosis	Clozapine, etc. Aminopyrine
Tissue pool

regards regulatory scrutiny and risk:benefit considerations, which justifies the detailed discussion below. Acute agranulocytosis is attributed to drugs in >70% of cases (Garb, 2007).

Mechanisms of idiosyncratic damage often do not relate to pharmacologic properties of the parent drug, which makes managing this risk a particular challenge to hematologists and toxicologists, as discussed later in this chapter. Preclinical toxicology is rarely predictive of these effects, which are generally detected and characterized following exposure of a large population to the drug (Dieckhaus et al., 2002; Szarfman et al., 2002). Idiosyncratic drug-induced neutropenia may be dose-related and involve a nonselective disruption of protein synthesis or cell replication resulting in agranulocytosis, as discussed below. Alternatively, and more commonly, it may not be dose-dependent (as qualified below), in which case it is usually thought to be allergic or immunologic in origin. The latter has been observed with many drugs, and is more frequently observed in women, older patients, and patients with a history of allergies (Dale, 2006).

Idiosyncratic xenobiotic-induced agranulocytosis may involve a sudden depletion of circulating neutrophils concomitant with exposure, which may persist as long as the chemical or its metabolites persist in the circulation. Hematopoietic function is usually restored when the chemical is detoxified or excreted. Suppression of granulopoiesis, however, is more prevalent than peripheral lysis of neutrophils and is asymptomatic unless sepsis supervenes (Pisciotta, 1973). The onset of leukopenia in the former is more gradual, but may be precipitous if lysis of circulating neutrophils also occurs. The pattern of the disease varies with the stage of granulopoiesis affected, which has been well defined for several drugs that cause bone marrow toxicity (Table 11-7). Toxicants affecting uncommitted stem cells induce total marrow failure, as seen in aplastic anemia, which generally carries a worse prognosis than chemicals affecting more differentiated precursors, such as CFU-G. It is thought that, in the latter case, surviving uncommitted stem cells eventually produce recovery, provided that the risk of infection is successfully managed during the leukopenic episodes (Pisciotta, 1973).

The incidence of drug-induced idiosyncratic agranulocytosis ranges from 2 to 15 cases per million patients exposed to drugs per year (Andres et al., 2002). While all drugs may be causative, the most commonly incriminated drugs include antithyroid agents and antibiotics, particularly sulfonamides (Andres et al., 2002; Berliner et al., 2004). An extensive case–control study on drug-induced agranulocytosis in Barcelona, Spain, followed 177 community cases (representing 78.73 million person-years), which were compared with 586 sex-, age-, and hospital-matched control subjects previously treated with the same putative drugs (Ibanez et al., 2005). The annual incidence was 3.46:1 million, which increased with age. The fatality and mortality rates were 7.0% and 0.24:1 million, respectively. The drugs most frequently implicated (in decreasing order of odds ratio) were ticlopidine hydrochloride (antithrombotic), calcium dobesilate (vasoprotective, antivaricose), antithyroid drugs, metamizole (analgesic), and spironolactone (diuretic). Other drugs associated with significant risk were pyrithyldione (psycholeptic), cinepazide (peripheral vasodilator), aprindine hydrochloride (antiarrhythmic), carbamazepine (antiepileptic), sulfonamides (intestinal antiinfective), phenytoin and phenytoin sodium (antiepileptic), β-lactam antibiotics, erythromycin stearate and erythromycin ethylsuccinate (anti-infectives), and diclofenac sodium (nonsteroidal anti-inflammatory). These drugs accounted for 68.6% of all cases.

Some drugs commonly implicated in the past, such as phenylbutazone (nonsteroidal anti-inflammatory, antirheumatic), chloramphenicol (antibiotic), and ticlopidine (antithrombotic), are used less commonly today due to this and other toxicity. Curiously, the incidence of this idiosyncratic reaction has not changed in the western hemisphere over the past 30 years, despite this evolution of putative drugs, suggesting that host factors are critical in the pathogenesis of the toxicity (Tesfa et al., 2009).

The severity of the neutropenia often causes severe sepsis or localized infections, such as sore throat, pneumonia, or various cutaneous infections. Prior to the use of hematopoietic growth factors, the mortality was 10% to 20% (Julia et al., 1991); with appropriate management it is now less than 5% (Andres et al., 2010).

Clozapine-induced agranulocytosis (CIAG) is unique, as a genetic predisposition has been established (Yunis et al., 1995; Turbay et al., 1997). Prior to an aggressive risk management program that included careful screening of prospective patients and early detection through hematologic monitoring, the incidence of agranulocytosis with this highly efficacious atypical antipsychotic was as high as 1% to 2%. This measure reduced the incidence to 0.38% and the mortality by 90% (Honigfeld et al., 1998). As reviewed, evidence from genetic association studies shows that the human leukocyte antigen (HLA) region plays a role in susceptibility to CIAG but multiple genes are likely to be involved (de With et al., 2017).

Mechanisms of Toxic Neutropenia Because cases of drug-induced neutropenia are relatively rare, sporadic, or transient, studies on the pathogenesis of this hematotoxicity have been limited. Toxic neutropenia has historically been classified according to mechanism as *immune-mediated* or *nonimmune-mediated.* There has long been a debate in the literature as to whether the principal mechanism of idiosyncratic drug-induced neutropenia (including agranulocytosis) is immune-mediated, or subsequent to the generation of toxic metabolites—both involving "preconditioning" through genetically determined immune responses to, or metabolism of, the putative drug, respectively. Both are consistent with the aforementioned early observations of Madison and Squier (1934) where transfusion of blood from affected patients to normal subjects induced neutropenia, presumably involving a humoral factor—presumably an antibody. There is now consensus that the mechanism of most drug-induced idiosyncratic diseases, including hepatotoxicity, Stevens–Johnson syndrome, agranulocytosis, and aplastic anemia, usually is immune-mediated, often involving altered proteins through reactive metabolite–mediated damage (Zhang et al., 2011). The Th17 T lymphocyte is emerging as an important mediator of this through a cellular immune mechanism demonstrated in aplastic anemia (de Latour et al., 2010; Platanias, 2010). Two hypotheses as to the mechanism (or alternative pathogeneses) for these idiosyncratic reactions that have emerged based on observations over the past 10 years include the *hapten hypothesis* and the *danger hypothesis* (Zhang et al., 2011). The former involves a reactive metabolite binding to a protein making it "foreign," which in turn induces an immune response that leads to the toxicity. The latter has a reactive metabolite damaging a cell, which elicits an immune response against the drug or an autoimmune response. The "perfect storm" in the rare individual in which these reactions occur is thought to be caused by preconditioned (or individual-specific) circumstances that drive both the metabolism of the drug and the immune reactions to the altered proteins. Consistent with these hypotheses is the fact that aplastic anemia and the more common agranulocytosis can be induced by many of the same drugs, most of which can be oxidized to reactive metabolites by the myeloperoxidase system of neutrophils, macrophages, and/or their precursors (Uetrecht, 1990).

The incidence of xenobiotic-induced immune neutropenia is considerably less than that of immune hemolytic anemias (Vandendries and Drews, 2006). In immune-mediated neutropenia, antigen–antibody reactions lead to destruction of peripheral neutrophils, granulocyte precursors, or both. As with RBCs, an immunogenic xenobiotic can act as a hapten, where the chemical must be physically present to cause cell damage, or may induce immunogenic cells to produce antineutrophil antibodies that do not require the drug to be present (Salama et al., 1989). Also like immune hemolytic anemia, drug-induced *autoimmune* neutropenia has been observed (Capsoni et al., 2005). Examples of drugs that have been implicated include fludarabine (antineoplastic, antimetabolite) (Stern et al., 1999), propylthiouracil (antithyroid) (Sato et al., 1985), and rituximab (antineoplastic, immunomodulator) (Voog et al., 2003). Xenobiotic-induced immune-mediated damage may also be cell-mediated (Pisciotta, 1973).

Detection of xenobiotic-induced neutrophil antibodies is also considerably more difficult than that of RBCs or platelets. This is because the neutrophil is relatively fragile and short-lived, and becomes easily activated (Palmblad et al., 2001). There is no good test for direct antigranulocyte antibodies comparable to the Coombs (antiglobulin) test. Several assays have been used, which can be grouped into four categories: those measuring endpoints of leukoagglutination, cytotoxic inhibition of neutrophil function, immunoglobulin binding, and those using cell-mediated mechanisms. Among the specific challenges these assays pose are the tendency of neutrophils to stick to each other in vitro, attract immunoglobulin nonspecifically to their surface, and reflect membrane damage through indirect and semiquantitative changes (Pisciotta, 1973). Most neutrophil-associated antibody assays applied clinically today employ flow cytometry, with the indirect granulocyte immunofluorescence test being the most promising (Sella et al., 2010). The reader is referred elsewhere for a more detailed discussion of other assays for immune-mediated neutrophil damage (Hagen et al., 1993; Palmblad et al., 2001; Nifli et al., 2006; Sella et al., 2010).

Some nonimmune-mediated toxic neutropenias have long been known to have a genetic predisposition (Pisciotta, 1973). Direct damage may cause inhibition of granulopoiesis or neutrophil function. It may entail failure to detoxify or excrete a xenobiotic or its metabolites, which subsequently build up to toxic proportions (Gerson et al., 1983; Uetrecht, 1990; Gerson and Meltzer, 1992). Some studies suggest that a buildup of toxic oxidants generated by leukocytes can result in neutrophil damage, as with the reactive intermediates derived from the interaction between clozapine and neutrophils. The resulting superoxide and hypochlorous acid production by the myeloperoxidase system are thought to contribute to clozapine-induced neutropenia (Uetrecht, 1990). Accumulation of nitrenium ion, a metabolite of clozapine (antipsychotic drug) that causes a depletion of ATP and reduced glutathione, rendering the neutrophil highly susceptible to oxidant-induced apoptosis, is now thought to be the principal mechanism of this disorder (Williams et al., 2000).

Examples of agents associated with immune and nonimmune neutropenia/agranulocytosis are listed in Table 11-8.

LEUKEMOGENESIS AS A TOXIC RESPONSE

Human Leukemia and Other Hematopoietic Malignancies

Leukemia is the sixth leading cause of cancer deaths among males and females in the United States (ACS, 2013). Leukemias arise when hematopoietic stem or progenitor cells (HSC/HPC) in the

bone marrow undergo uncontrolled proliferation or clonal expansion and cannot differentiate normally into mature blood cells (Sawyers et al., 1991). Leukemias are broadly characterized as myeloid or lymphoid depending on the lineage of origin. Based on the stage of differentiation and rate of clonal expansion, they are also characterized as acute (rapid onset, immature blast cells) or chronic (more gradual onset over months or years, more mature cells). Using this basic classification, four major types of leukemia are commonly referred to —acute lymphoblastic leukemia (ALL), acute myeloid leukemia (AML) also known as acute nonlymphocytic leukemia (ANLL), chronic lymphoblastic leukemia (CLL), and chronic myeloid leukemia (CML). Within these categories numerous subtypes exist and are classified according to morphologic, cytogenetic, immunophenotypic, and more recently, molecular characteristics, according to the French-American-British (FAB) or World Health Organization (WHO) classification systems (Bennett et al., 1985; Levine and Bloomfield, 1992; WHO, 2001, 2008; Haferlach et al., 2005).

The WHO classification system provides a comprehensive updated diagnostic framework for classifying CLL, CML, ALL, AML, myeloproliferative neoplasms (MPN), and myelodysplastic syndromes (MDS), along with various subtypes of these disorders (Vardiman et al., 2002; Vardiman et al., 2009; Campo et al., 2011; Arber et al., 2016; Bennett, 2016; Swerdlow et al., 2016). The program identifies new entities and variants based on emerging findings from clinical and scientific studies. The WHO AML classification utilizes, among other characteristics, molecular features, particularly recurrent cytogenetic abnormalities and specific gene mutations. In the WHO classification, the term "myeloid" includes all cells belonging to the granulocytic (neutrophil, eosinophil, basophil), monocytic/macrophage, erythroid, megakaryocytic, and mast cell lineages. In this scheme, a myeloid neoplasm with 20% or more blasts in the blood or marrow is considered to be AML. AML can arise from a pre-existing MDS, which represent myeloid clonal hemopathies with relatively heterogeneous spectrums of presentation. The major clinical problems in these disorders are morbidities caused by cytopenias and the potential for MDS to evolve into AML. MDS are a diverse group of bone marrow disorders in which the bone marrow does not produce enough healthy blood cells. MDS is primarily a disease of the elderly (most patients are older than age 70) (Rollison et al., 2008). CML is now considered a form of MPN (Arber et al., 2016).

Therapy-Related leukemia More than half of all leukemias occur in people with no obvious prior exposures of relevance and are termed de novo leukemias. *Secondary leukemias* are those that develop in individuals who have previously been exposed to radiation, industrial chemicals, or chemotherapeutic drugs or who previously had an MDS/MPN. *Therapy-related MDS* and *AML* (t-MDS and t-AML) arise following cytotoxic therapy for an unrelated malignancy or autoimmune disease. They account for approximately 10% of all cases of AML and MDS (WHO, 2008) and are distinct from their de novo counterparts with regard to onset, prognosis, and response to therapy. In a recent national study in Denmark, the frequencies of secondary AML and t-AML were 19.8% and 6.6%, respectively (Granfeldt Ostgard et al., 2015). In the United States t-AML is thought to accounts for 10% of all diagnosed AML (Churpek and Larson, 2013).

Childhood Leukemia Adult leukemias are predominantly myeloid and originate in pluripotent stem or progenitor cells. In contrast, 30% of pediatric acute leukemias are AML and 70% are ALL. Childhood ALL (cALL) arises in naïve pre-B (B-ALL) or pre-T progenitor cells (T-ALL) that are present in large numbers in early life and undergoing immune education. B-ALL can be stratified by differentiation stage; for example, proB-ALL or preB-ALL) (Wiemels, 2012). Childhood AML can affect both immature (FAB subtype M0) and mature lineage-committed types, such as erythroblastic or megakaryoblastic leukemia (subtypes M6 and M7, respectively). ALL and AML can be further stratified according to molecular cytogenetics (Pandita et al., 2015; Yohe, 2015), which is related to prognosis. Studies have shown that the underlying aberrations occur in two distinct stages, with oncogenic fusion proteins generated in utero, and subsequent cooperating hits of a genetic, epigenetic, or immune nature occurring after birth (Wiemels, 2008). Childhood leukemia is the second highest cause of cancer death in children 0 to 14 years old and first in those 15 to 19 years old (ACS, 2017).

General Mechanisms of Leukemogenesis

As illustrated in Fig. 11-8, leukemogenesis is a multistep process involving the acquisition of various combinations of chromosomal, genetic, and epigenetic aberrations that transform a normal stem cell into a leukemic stem cell (LSC) (Look, 2005; De Kouchkovsky and Abdul-Hay, 2016; Gore and Weinstein, 2016; Khaled et al., 2016; Bullinger et al., 2017). The resulting altered gene expression patterns disrupt critical hematopoietic processes such as signal transduction, alternative splicing, and epigenetics, and give rise to cellular phenotypes such as increased proliferation or survival, block of differentiation, and immortalization (Kitamura et al., 2016). Combinations of aberrations inform the WHO classification system (Vardiman et al., 2009; Campo et al., 2011; Bennett, 2016).

Chromosomal Aberrations Several kinds of chromosomal aberration can occur and they alter the function of genes in the affected region. A translocation is an abnormality in which chromosome regions are swapped between chromosomes. Translocations are designated as t(a;b), where part of chromosome a is translocated to

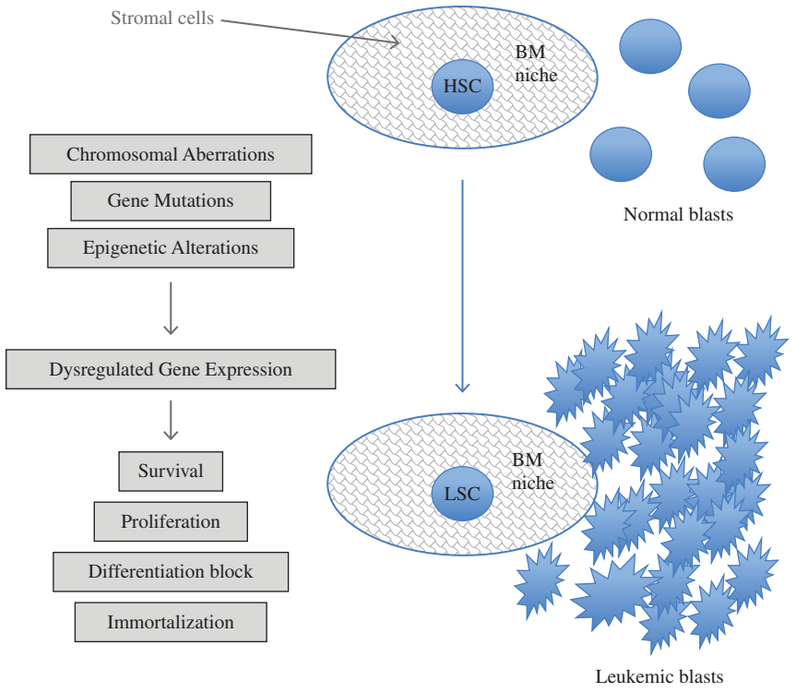

Figure 11-8. *Pathogenesis of leukemia.* Leukemogenesis is a multistep process involving the acquisition of various combinations of chromosomal, genetic, and epigenetic aberrations that transform a normal HSC into an LSC. The resulting altered gene expression patterns disrupt critical hematopoietic processes such as signal transduction, alternative splicing, and epigenetics, and give rise to cellular phenotypes such as increased proliferation or survival, block of differentiation, and immortalization. Thus, the bone marrow becomes replete with leukemic blasts and LSCs that replenish them.

chromosome b and vice versa. Chromosomal deletion, designated as del(#p or #q), involves the loss of a chromosomal region and an inversion, designated as inv(#) involves the end-to-end reversal of a region within a chromosome.

Many leukemia patients exhibit chromosomal alterations in their tumor cells (Pedersen-Bjergaard et al., 2006; Pedersen-Bjergaard et al., 2008; Mrozek et al., 2009; Vardiman et al., 2009; Qian et al., 2010; Campo et al., 2011; De Kouchkovsky and Abdul-Hay, 2016; Saleem and Yusoff, 2016; Taylor et al., 2017). Chromosomal aberrations in AML (Yang et al., 2017) and ALL (Jabbour et al., 2015) have been reviewed. Common aberrations in AML include loss or gain of one or more chromosomes (e.g., monosomy 7 and trisomy 8, respectively), recurrent chromosomal translocations such as t(8;21) and t(15;17), deletions, and inversions such as inv(16). In ALL, t(9;22) frequently occurs in adults whereas t(12;21) is more common in children.

Altered function of the fusion genes resulting from a translocation may have consequent effects on growth and maturation. For example, t(8;21)—which occurs in 12% of de novo AML and up to 40% of AML FAB subtype M2—fuses the RUNX1 gene on chromosome 21 with the RUNX1T1 gene on chromosome 8. The fusion product blocks maturation of the myeloid progenitor cells by interfering with transcription of RUNX1 target genes. t(12;21), present in around 25% of childhood precursor B cell ALL (Inaba et al., 2013), results in the ETV6-RUNX1 fusion gene which generates an aberrant transcription factor that represses gene expression (Teppo et al., 2016).

Gene Mutations Mutations in a recurring set of genes in HSC/HPC (Mehdipour et al., 2015; Marjanovic et al., 2016; Shin et al., 2016) that alter cell growth, apoptosis, differentiation, epigenetic processes, and tumor suppression characterize AML (Cancer Genome Atlas Research, 2013; Dohner et al., 2015). The most common recurrent AML mutations are in FLT3, NPMI, DNMT3A, IDH1, IDH2, TET2, and RUNX1 (Cancer Genome Atlas Research, 2013; Papaemmanuil et al., 2016). Mutations in ASXL1, DNMT3A, TET2, and IDH1/2 lead to epigenetic deregulation and are considered to be early initiating events (Chan and Majeti, 2013; Hirsch et al., 2016). Studies using recent next generation sequencing technologies have shown that over 70% of AML cases have mutations in genes encoding DNA methylation or histone modifiers (Mehdipour et al., 2015). Alternative splicing is an important contributor to the diversity and function of the hematopoietic cellular repertoire (Pritsker et al., 2005). Mutations in genes such as SRSF2, SF3B1, and U2AF1 lead to aberrant splicing, a major driver of leukemogenesis (Hahn et al., 2015).

Epigenetic Modifications Epigenetic modifications likely play an important role in leukemogenesis (Pedersen-Bjergaard et al., 2006; Nervi et al., 2008; Liu et al., 2011) and altered epigenetic signatures such as DNA methylation and miRNA expression have also been seen in many types of leukemia (Zheng et al., 2004; Pedersen-Bjergaard et al., 2006; Nervi et al., 2008; Khalaj et al., 2014; Yeh et al., 2016). Long noncoding RNAs, important regulators of gene expression, may also contribute to the initiation and development of AML (Wei and Wang, 2015).

Leukemic Stem Cells and the Bone Marrow Niche Leukemia-related aberrations arise in HSC/HPC and in other cellular components of the bone marrow niches where HSC/HPC reside. The acquisition of increased self-renewal capability in HSC/HPC leads to the generation of leukemic stem cells (LSCs) resembling multilineage progenitors that initiate and maintain AML (Passegue et al., 2003; Reinisch et al., 2015). LSCs can evade programmed

cell death and removal. For example, altered cell-surface expression of CD47 on AML LSCs inhibits phagocytosis by macrophages (Majeti et al., 2009); CD47 is also abnormally expressed in MDS patients at a high-risk of progressing to AML (Jiang et al., 2013). Disruption of aryl hydrocarbon receptor (AhR) signaling, which regulates stem cell cycling, regulation, and quiescence, may play a role in the etiology and/or progression of certain hematopoietic diseases (Casado et al., 2011). Toxicity-induced aberrations in stromal cells may lead to disruption of signals from the bone marrow niche (Ehninger and Trumpp, 2011). The bone marrow niche microenvironment enables the survival and proliferation of AML blasts (Shafat et al., 2017).

Leukemogenic Agents and Mechanisms of Leukemogenesis

Around 25% of the 100 agents identified as human carcinogens in humans by IARC are known to induce lymphohematopoietic cancers (IARC, 2010). Of the 25%, many are antineoplastic drugs, but the list includes industrial chemicals, various forms of radiation, immunosuppressive drugs, and infectious agents. The established nongenetic causes of AML and MDS are ionizing radiation, cytotoxic chemotherapeutic drugs, tobacco smoking, and occupational exposure to benzene or high levels of formaldehyde. Some studies suggest that smoking a pack-a-day of cigarettes increases the risk of AML by about 50% or 1.5-fold (Moorman et al., 2002; Kasim et al., 2005). Smoking is, therefore, a relatively weak, though established cause of AML as it doesn't cause a doubling of the risk in most studies even at high levels of exposure. Pesticide exposure and obesity have also been associated with AML in a number of studies but not consistently. They remain possible causes of AML.

Table 11-9 provides details of known (IARC Group 1) leukemogenic agents and their likely modes of action, adapted from EPA data (U.S. EPA, 2012).

Cytotoxic Chemotherapeutic Agents Today it is thought that approximately 10% of AMLs in the United States are therapy-related (Churpek and Larson, 2013). The main associated therapeutic agents include alkylating agents, topoisomerase II inhibitors, antimetabolite, and antitubulin drugs. The risk of t-MDS/t-AML varies considerably with the therapeutic regimen and ranges from 0.8% to 24% (U.S. EPA, 2012; Bhatia, 2013). Alkylating agents, such as nitrogen mustards, and antimetabolites induce bone marrow damage primarily characterized by pancytopenia, similar to the effects of ionizing radiation. The main dose-limiting toxicity associated with the majority of anticancer drugs is therapy-related myelosuppression (Parchment et al., 1998).

Most *alkylating agents* used in cancer chemotherapy (e.g., melphalan, cyclophosphamide, nitrogen mustard, busulfan, chlorambucil, carboplatin, cisplatin, dacarbazine, procarbazine, carmustine, mitomycin C, thiotepa, lomustine) can cause MDS and/or AML (Bhatia, 2013; Zahid et al., 2016). *Alkylating agents* typically induce AMLs that are preceded by a myelodysplastic phase and are often characterized by loss of all or part of chromosome 5 or 7, complex karyotypes, and mutations in p53 (Le Beau et al., 1986; Karp and Sarkodee-Adoo, 2000; Churpek and Larson, 2013; Zahid et al., 2016). Monofunctional alkylating agents, such as nitrosoureas, dacarbazine and temozolomide, transfer an alkyl group to DNA bases to form lesions that result in the formation of mutations, secondary DNA double-stranded breaks, and eventual cytotoxicity (Drablos et al., 2004; Allan and Travis, 2005; Kaina et al., 2007). Bifunctional alkylators, such as cyclophosphamide, melphalan and chlorambucil, induce the formation of cross-links within and between DNA lesions in addition to alkylated base lesions (Sill et al., 2011). The resulting double-stranded DNA breaks can lead to chromosomal translocations, insertions, inversions, and loss-of-heterozygosity (Richardson and Jasin, 2000; Helleday et al., 2008).

Topoisomerase II poisons kill cells by increasing levels of covalent enzyme-cleaved DNA complexes that are normal reaction intermediates. Drugs such as etoposide, doxorubicin, and mitoxantrone are used to treat a variety of cancers and autoimmune conditions. Unfortunately, their use is also associated with the development of specific leukemias. Regimens that include etoposide or doxorubicin are linked to the occurrence of AMLs that feature rearrangements at chromosomal band 11q23 (Pendleton et al., 2014). Similar rearrangements are seen in infant leukemias and are associated with gestational diets that are high in naturally occurring topoisomerase II-active compounds (Spector et al., 2005). Finally, regimens that include mitoxantrone and epirubicin are linked to acute promyelocytic leukemias that feature t(15;17) rearrangements (Joannides et al., 2011). Compared with alkylating agents, topoisomerase II poison-associated AMLs have shorter latencies and often lack a preceding myelodysplastic phase.

Patients treated with the *antimetabolite drugs* azathioprine, 6-thioguanine, and 6-mercaptopurine have an increased risk of developing AML (Bo et al., 1999; Karran, 2006; Yenson et al., 2008). Risks are higher in patients with low thiopurine *S*-methyltransferase activity and may also involve aberrant mismatch repair and microsatellite instability (Bo et al., 1999; Karran, 2006). Many patients treated with antimetabolite drugs have loss of chromosome 7 or partial loss of chromosome 5 or 7 ($5q^-$ or $7q^-$) (Yenson et al., 2008).

As t-AML is the dominant hematopoietic disorder associated with drug or chemical exposure (Casciato and Scott, 1979; Anderson et al., 1981; Irons, 1997), followed by t-MDS, these diseases may represent a continuum of toxic response (Irons, 1997; Look, 2005). In 2008, Pedersen-Bjergaard reviewed the genetics of de novo MDS/AML and t-MDS/AML and found strong similarities in cytogenetic abnormalities and gene mutations (Pedersen-Bjergaard et al., 2008). However, more t-AML and t-MDS cases (up to 50%) have a *complex karyotype* (more than three aberrations) (Mauritzson et al., 2000; Rossi et al., 2000). Subtypes with frequent, high-risk cytogenetic aberrations have a poorer prognosis (Godley and Larson, 2008). Pederson-Bjergaard identified eight separate pathways that appear to lead either directly to t-AML or t-MDS/AML (Pedersen-Bjergaard et al., 2006). The direct induction of oncogenic aberrations, genetic instability, and accumulation of complex aberrations, represent one mechanism of t-AML/MDS. Recent experimental and clinical data show that the selection by chemotherapeutic drugs of a pre-existing treatment-resistant HSC clone with TP53 mutation may be another important mechanism (Wong et al., 2015). Specific TP53 mutations were found at low frequency in hematopoietic cells 3 to 6 years before the onset of therapy-related disease. TP53 is the most frequently mutated gene in t-AML/t-MDS, being present in one-third of patients (Christiansen et al., 2001; Shih et al., 2013).

Radiation Exposure to ionizing radiation has been associated with several types of leukemia (IARC, 2000, 2001; UNSCEAR, 2000a, 2000b; Ron, 2003; NRC, 2006). Children who survived the atomic bombs in Hiroshima and Nagasaki were at an elevated risk of radiation-induced leukemia (Ron et al., 1994; Preston et al., 2004). Leukemogenesis associated with radiation involves myelotoxicity, immune suppression, chromosomal aberrations, and genetic mutations. Increased risk of leukemia has also been reported following the use of radiation for diagnostic tests, for the treatment of benign diseases, and following radiotherapy for cancer (Ron, 1998, 2003).

Table 11-9

Characteristics of Selected Known Human Leukemia-Inducing Agents (IARC Group 1)

AGENT	CLASS	LEUKEMIA TYPE	MYELO-TOXICITY	CHROMOSOME ABERRATIONS	ACTIVATION	PRIMARY MECHANISM
(1-(2-)Chlorethyl)-3-(4-methylcyclohexyl) nitrosourea (Methyl-CCNU, Semustine)	Therapeutic agent	ANLL	+	n/d	Degrades to direct- acting alkylating and carbamoylating agents	DNA reactive; mutation resulting from DNA binding and/or chromosomal alterations
1,3-Butadiene	Industrial chemical	Lympho-hematopoietic cancers	−	−	Bioactivated to mono- and bifunctional alkylating agents	DNA reactive; mutation resulting from DNA binding and/or chromosomal alterations
1,4-Butanediol dimethanesulfonate (Busulfan, Myleran)	Therapeutic agent	ANLL	+	SCA	Direct-acting bifunctional alkylating agent	DNA reactive; mutation resulting from DNA binding and/or chromosomal alterations
Benzene	Industrial and environmental chemical	ANLL, ALL, CLL	+	SCA, aneuploidy	Metabolized into reactive protein and DNA-binding species	Likely multiple metabolites and modes of action involved
Chlorambucil	Therapeutic agent	ANLL	+	SCA	Direct-acting bifunctional alkylating agent	DNA reactive; mutation resulting from DNA binding and/or chromosomal alterations
Cyclophosphamide	Therapeutic agent	ANLL	+	SCA	Bioactivated to bifunctional alkylating agent and acrolein	DNA reactive; mutation resulting from DNA binding and/or chromosomal alterations
Etoposide	Therapeutic agent	ANLL	+	MN	Topoisomerase II- poison	Mutation resulting from chromosomal breakage and translocations
Formaldehyde	Industrial and environmental chemical	Myeloid	+/−	+/−	Direct-acting, forms DNA-protein cross-links	Unknown, possibly mutation resulting from DNA binding and/or chromosomal alterations
Melphalan	Therapeutic agent	ANLL	+	SCA	Direct-acting bifunctional alkylating agent	DNA reactive; mutation resulting from DNA binding and/or chromosomal alterations

MOPP therapy	Therapeutic agent combination	ANLL	+	SCA	A direct-acting bifunctional and an indirect monofunctional alkylating agent, a microtubule inhibitor, and a glucocorticoid	DNA reactive; mutation resulting from DNA binding and/or chromosomal alterations
Paint (occupation, maternal)	Occupational exposure	Childhood ALL	n/d	n/d	Possibly DNA reactive chemicals	Unknown, assumed to be mutation resulting from DNA binding and/or chromosomal alterations and/or immunosuppression
Radiation (alpha, beta)	Therapeutic, energy, and military uses	ANLL, CML, ALL	+	SCA	Direct and indirect DNA damage	Mutation resulting from DNA damage and/or chromosomal alterations
Radiation (x-ray, gamma)	Therapeutic, energy, and military uses	ANLL, CLL, ALL	+	SCA	Direct and indirect DNA damage	Mutation resulting from DNA damage and/or chromosomal alterations
Rubber manufacturing occupation	Occupational exposure	Leukemia	n/d	SCA	Possibly DNA reactive chemicals	Unknown, assumed to be mutation resulting from DNA binding and/or chromosomal alterations and/or immunosuppression
Thio-TEPA (tris(1-aziridinyl)-phosphine)	Therapeutic agent	Leukemia	+	SCA	Direct-acting trifunctional alkylating agent. Also, metabolized to monofunctional alkylating agent aziridine	DNA reactive; mutation resulting from DNA binding and/or chromosomal alterations
Tobacco smoking	Lifestyle use	ANLL	n/d	SCA	Direct and indirect DNA damage	Mutation resulting from DNA damage and/or chromosomal alterations
Tobacco smoking (parental)	Parental use	Childhood ALL	n/d	n/d	Direct and indirect DNA damage	Mutation resulting from DNA damage and/or chromosomal alterations
Treosulfan	Therapeutic agent	ANLL	+	n/d	Converts to a mono- and bifunctional alkylating agent	DNA reactive; mutation resulting from DNA binding and/or chromosomal alterations

Abbreviations: n/d, not determined, insufficient data; SCA, structural chromosome aberrations.

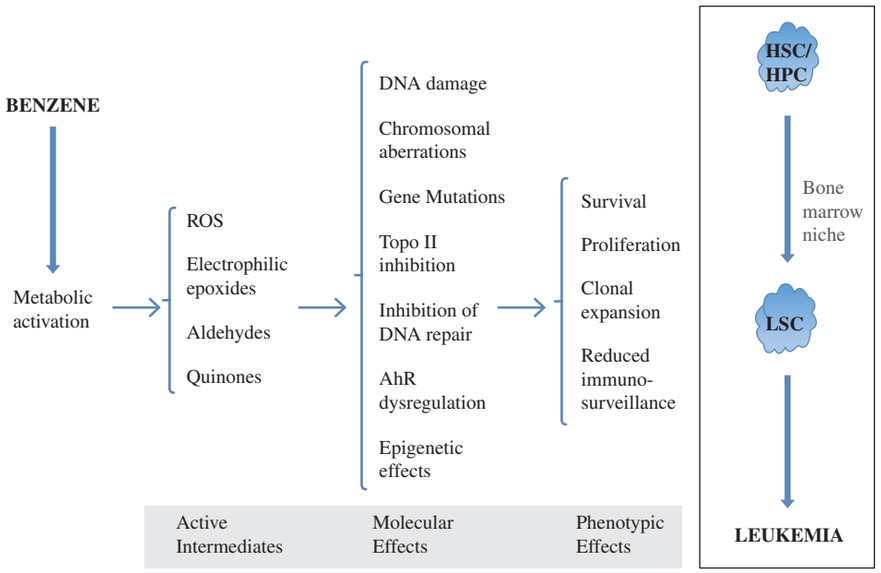

Figure 11-9. *Probable mechanism of leukemia induction by benzene.* Schematic representation of the active intermediates of benzene toxicity and their molecular and phenotypic effects in HSC/HPCs and bone marrow niche cells that lead to the generation of LSCs and leukemia development.

Occupational and Environmental Exposures Benzene and formaldehyde are among the few occupational/environmental exposures that have been classified as known human leukemogens (Table 11-9).

Benzene Benzene is an industrial chemical, a component of gasoline and cigarette smoke, a contaminant in mixtures of organic solvents and glues, and a widespread environmental contaminant. Despite its regulation, it has recently been estimated that exposure to benzene may cause as much as 8% to 16% of the AML and MDS cases in the general U.S. population (Poynter et al., 2017). The hematotoxic properties of benzene were first demonstrated more than a century ago in 1897 (Santesson, 1897), and by the 1920s it was well known that benzene was a dangerous toxicant in the workplace (Selling, 1916; Hamilton, 1931). The first case report of benzene-induced leukemia was published in 1928 (Delore and Borgomano, 1928), multiple additional case reports and series appeared in the 1930s to 1960s. In 1961, Cronkite described benzene as one of two known leukemogens (Cronkite, 1961) the other being ionizing radiation and by the late 1970s specifically designed epidemiological studies had clearly established benzene as a cause of human leukemia (Infante et al., 1977; Rinsky et al., 1981). A number of specific studies have established the relationship between benzene exposure and MDS (Strom et al., 2005; Lv et al., 2011; Schnatter et al., 2012; Copley et al., 2017).

Multiple metabolites and mechanisms are likely to be involved in benzene-induced leukemogenesis (ATSDR, 2007; IARC, 2012; McHale et al., 2012), as illustrated in Fig. 11-9. Benzene is metabolized in the liver to form reactive metabolites such as benzene oxide, benzene dihydrodiol epoxide, and the phenols: catechol, benzenetriol, and hydroquinone, which are subsequently metabolized in the bone marrow to produce benzoquinone metabolites (Snyder and Hedli, 1996). Reactive species include benzene epoxide, benzene dihydrodiol epoxide, *t,t*-muconaldehyde, 1,2- and 1,4-benzoquinone. Genotoxicity and myelotoxicity are induced by benzene metabolites and by reactive oxygen species (ROS) formation via redox cycling of reactive intermediates (Sammett et al., 1979; Kolachana et al., 1993; Valentine et al., 1996; Ahmad Khan, 2007).

Benzene targets pluripotent bone marrow HSC and reduces the numbers of circulating blood cells in experimental animals (Snyder, 1988). Sustained exposure to high levels in people can lead to pancytopenia and, in severe cases, aplastic anemia (Goldstein, 1977; Aksoy, 1988; Snyder, 2012). In occupationally exposed workers including those exposed to levels below the U.S. occupational exposure limit, hematotoxicity—manifest as reduced numbers of total white blood cells, granulocytes, lymphocytes, B cells, and platelets, was reported (Lan et al., 2004). The number of circulating hematopoietic myeloid progenitor cells was also suppressed.

Benzene is mutagenic to spleen and bone marrow in mice (Ward et al., 1992; Mullin et al., 1995; Provost et al., 1996; Albertini et al., 2010). However, increased gene-duplicating mutations rather than gene-inactivating mutations were detected in the glycophorin A gene in exposed workers (Rothman et al., 1995). Benzene induces structural chromosomal aberrations, and to a lesser degree numerical aberrations, in experimental animals (Eastmond et al., 2001; ATSDR, 2007; IARC, 2012). Chromosome breakage and aneuploidy have been seen in multiple studies of the lymphocytes of exposed workers (Zhang et al., 2002). Benzene exposure has been associated with higher levels of chromosomal changes commonly observed in AML, including 5q/5 or 7q/7, þ8 and t(8;21) in the peripheral blood lymphocytes of highly exposed workers (Smith et al., 1998; Zhang et al., 1999; Zhang et al., 2002). Monosomy 7 and 8 were produced in a dose-dependent manner in blood progenitor cells (Zhang et al., 2012). Benzene-induced AMLs share cytogenetic aberrations with t-AML induced by alkylating agents (Irons and Stillman, 1996; Zhang et al., 1998; Zhang et al., 2012) and topoisomerase II inhibitors (Smith et al., 1998). Benzene and its metabolites can inhibit topoisomerase II in vitro and in vivo (Chen and Eastmond, 1995; Eastmond et al., 2001; Mondrala and Eastmond, 2010).

As well as targeting critical genes and pathways through the induction of genetic and chromosomal abnormalities and genomic instability in HSC/HPC, additional mechanisms of benzene-induced

hematotoxicity and leukemogenesis have been proposed, including altered proliferation and differentiation of HSCs, oxidative stress, altered epigenetics and transcriptomics, bone marrow niche dysregulation, altered AhR signaling, and reduced immunosurveillance (McHale et al., 2012; Greim et al., 2014).

Formaldehyde Formaldehyde is an important industrial chemical in the global economy but also a ubiquitous pollutant in the environment. It is used as a tissue preservative and in the manufacture of many consumer products, including pressed wood furniture and flooring. Globally, millions of people are occupationally and environmentally exposed to formaldehyde (Zhang et al., 2009). Formaldehyde is classified as a leukemogen by IARC and United States National Toxicology Program, particularly for its association with myeloid neoplasms, based on epidemiological and mechanistic evidence (IARC, 2012).

Occupational exposure to formaldehyde in healthy workers led to a decrease in complete blood cell counts and reduced numbers of lymphocytes, granulocytes, and platelets (Zhang et al., 2010c), aneuploidy of chromosome 5 and 7, and structural aberrations in chromosome 5 in myeloid progenitor cells (Zhang et al., 2010c; Lan et al., 2015). Toxicity of formaldehyde to blood-forming systems, including mature blood cells, bone marrow cells, and hematopoietic stem/progenitor cells (HSCs/HPCs), has been further examined in experimental animal models. Formaldehyde exposure in vivo reduced the number of nucleated bone marrow cells and the counts of granulocyte-macrophage colony-forming units (CFU-GM) colonies cultured from mouse bone marrow (Wei et al., 2017), but increased the number of bone marrow megakaryocytes (Zhang et al., 2016).

Formaldehyde is genotoxic and induces DNA damage in the form of DNA adducts (Lu et al., 2011), protein-adducts (Regazzoni et al., 2017), and DNA-protein cross-links (DPCs). It also induces chromosome changes, including chromosomal aberrations (CA), sister chromatid exchanges (SCEs), and micronuclei (MN) (Zhang et al., 2010a). These changes have been reported in treated human cells in vitro, in exposed animals, and in the peripheral blood lymphocytes of exposed people, though some inconsistent results exist in the literature (Zhang et al., 2010a).

The mechanisms of formaldehyde-induced leukemogenesis are not well understood. Due to its highly reactive nature, formaldehyde is unlikely to mimic classic leukomogens (such as benzene) and exert hematotoxic/genotoxic damage directly in the bone marrow. Potential alternative mechanisms have been proposed in which inhaled formaldehyde could act by inducing mutations or pre-mutagenic lesions in (1) HSCs and HPCs circulating in peripheral blood proximal to the lungs; or (2) primitive pluripotent stem cells present within the nasal turbinates and/or olfactory mucosa (Zhang et al., 2009). In both cases, the damaged stem cells could travel to the bone marrow and initiate leukemogenesis, either through normal trafficking or trafficking enhanced by formaldehyde-induced cytotoxicity. The recent finding that the lung is a reservoir for HSC/HPC, capable of moving bidirectionally between the lung and bone marrow (Lefrancais et al., 2017), presents the possibility of a third alternative mechanism in which formaldehyde damages HSC/HPC in the lung. The mechanisms of formaldehyde-induced leukemogenesis require experimental validation.

Causes of Childhood Leukemia Multiple risk factors influence childhood leukemia, particularly in utero and in early life. In utero exposure to low-dose radiation from medical x-rays is a well-known risk factor (Linet et al., 2009). Exposures to pesticides through home use or paternal occupational exposure, paternal preconception smoking, solvents, and traffic emissions also have consistently been associated with disease risk (Metayer et al., 2013; Boothe et al., 2014; Filippini et al., 2015; Carlos-Wallace et al., 2016; Whitehead et al., 2016). In addition, there is evidence of associations between childhood leukemia and several different potential metrics of benzene exposure (Carlos-Wallace et al., 2016). Infant AML with chromosome 11q23 rearrangements is associated with maternal diets high in naturally occurring topoisomerase II-active agents, including soy. Apart from the latter, the mechanisms underlying these associations are unclear. The most common translocation in ALL, ETV6-RUNX1, appears to be associated with parental smoking (Metayer et al., 2013) and home paint use (Scelo et al., 2009). Prenatal and early-life tobacco smoke exposure was recently shown to increase the frequency of ALL-associated gene deletions in children who develop ALL (de Smith et al., 2017).

Factors That Modulate Leukemia Risk

Modifiers of leukemia risk by leukemia-inducing agents and their importance to risk assessment have been discussed previously (U.S. EPA, 2012). These include metabolism, pharmacokinetics, DNA-adduct type and repair, as well as individual and age-related susceptibility factors. For example, genetic variation can modulate the response to hematotoxic and leukemogenic agents. In multiple candidate gene association studies, susceptibility to benzene-induced hematotoxicity has been shown to be mediated by polymorphisms in genes involved in benzene metabolism, oxidative stress, DNA repair and genomic maintenance, innate immunity, cytokines, cellular adhesion molecules (Lan et al., 2004, 2005, 2009; Shen et al., 2011; Carbonari et al., 2016). One of these polymorphisms in the enzyme NAD(P)H:quinone oxidoreductase (NQO1) lowers or eliminates its activity and increases susceptibility to benzene-induced hematotoxicity (Rothman et al., 1997), as well as overall risk of de novo AML (Li et al., 2014) and therapy-induced myeloid neoplasms (Larson et al., 1999). Thus, knowing an AML case's NQO1 genetic variants does not help a differential diagnosis distinguish whether an AML is related to benzene exposure or arose de novo idiopathically from no known cause.

TOXICOLOGY OF PLATELETS AND HEMOSTASIS

Hemostasis is a multicomponent system responsible for preventing the loss of blood from sites of vascular injury and maintaining circulating blood in a fluid state. Loss of blood is prevented by formation of stable hemostatic plugs mediated by the procoagulant arm of hemostasis. This procoagulant response is normally limited to sites of vascular injury by the multicomponent regulatory arm of hemostasis. The dynamically modulated balance between procoagulant and regulatory pathways permits a rapid, localized response to injury. The major constituents of the hemostatic system include circulating platelets, a variety of plasma proteins, and vascular endothelial cells. The role of other cells in hemostasis, especially leukocytes, has been documented (Lane et al., 2005; Monroe and Hoffman, 2005). Alterations in these components or systemic activation of this system can lead to the clinical manifestations of deranged hemostasis, including excessive bleeding and thrombosis. The hemostatic system is a frequent target of therapeutic intervention as well as inadvertent expression of the toxic effect of a variety of xenobiotics. This section briefly reviews the inadvertent effects of xenobiotics on hemostasis and the toxic effects of chemicals used to manipulate the hemostatic system.

Table 11-10

Mechanism of Immune-Mediated Thrombocytopenia

PROBABLE MECHANISM	PROTOTYPIC AGENT	ANTIGEN/EPITOPE	PLATELET EFFECT	CLINICAL EFFECT
Hapten-directed antibody	Penicillin	Drug	Opsonization ↑ Clearance	Bleeding
Acquired antibody to drug-induced epitope	Quinidine	Drug–GP Ib/IX/V Drug–GP IIb/IIIa	Opsonization ↑ Clearance	Bleeding
Natural antibody to drug-induced epitope	Abciximab	GP IIb/IIIa	Opsonization ↑ Clearance	Bleeding
Induction of autoimmune antibodies	Gold	Platelet membrane	Opsonization ↑ Clearance	Bleeding
Immune complex	Heparin	PF 4–heparin complex	Platelet activation and aggregation ↑ Clearance	Thrombosis
Thrombotic thrombocytopenic purpura (TTP)	Ticlopidine	vWF-cleaving protease	Platelet activation Platelet aggregation ↑ Clearance	Microvascular thrombosis Microangiopathic hemolytic anemia
Hemolytic uremic syndrome (HUS)	Mitomycin	Unknown	Platelet activation and aggregation ↑ Clearance	Microvascular thrombosis Microangiopathic hemolytic anemia Renal failure

Toxic Effects on Platelets

The Thrombocyte Platelets are essential for formation of a stable hemostatic plug in response to vascular injury. They initially adhere to the damaged wall through binding of von Willebrand factor (vWF) with the platelet glycoprotein Ib/IX/V (GP Ib/IX/V) receptor complex (Jurk and Kehrel, 2005). Ligand binding to GP Ib/IX/V or interaction of other platelet agonists (e.g., thrombin, collagen, ADP, thromboxane A_2) with their specific receptors initiates biochemical response pathways that lead to shape change, platelet contraction, platelet secretion of granule contents, activation of the GP IIb/IIIa receptor, and externalization of phosphatidylserine (Jurk and Kehrel, 2005). Activation of the GP IIb/IIIa receptor permits fibrinogen and other multivalent adhesive molecules to form cross-links between nearby platelets, resulting in platelet aggregation. Xenobiotics may interfere with the platelet response by causing thrombocytopenia or interfering with platelet function; some agents are capable of affecting both platelet number and function.

Thrombocytopenia Like anemia, thrombocytopenia may be due to decreased production or increased destruction. Thrombocytopenia is a common side effect of intensive chemotherapy, due to the predictable effect of antiproliferative agents on hematopoietic precursors, including those of the megakaryocytic lineage. It is a clinically significant component of idiosyncratic xenobiotic-induced aplastic anemia, as discussed previously. Indeed, the initial manifestation of aplastic anemia may be mucocutaneous bleeding secondary to thrombocytopenia.

Exposure to xenobiotics may cause increased immune-mediated platelet destruction through several mechanisms (Table 11-10). Initially, immune thrombocytopenia was thought to be an antibody-mediated disease (Harrington et al., 1951) with either the xenobiotic acting as a hapten after binding to the platelet surface or by the xenobiotic causing a neoepitope to be formed on a platelet membrane glycoprotein. These actions were thought to elicit an antibody response, with the responding antibody binding resulting in removal of the platelet from the circulation by the mononuclear phagocytic system. However, a variety of lymphocyte abnormalities are also found in patients with immune thrombocytopenia, including skewing of T helper cells to an autoimmune phenotype, poor activity of regulatory T cells or regulatory B cells, and also direct killing of platelets by cytotoxic T cells (Cooper, 2017), suggesting an important role for T and B cells in xenobiotic-induced immune thrombocytopenia. Antibodies and T cells may also attack megakaryocytes, causing reduced platelet production (Cooper, 2017).

More than 100 drugs have been associated with causing immune thrombocytopenia, but recent reviews of available data show that carbamazepine, eptifibatide, ibuprofen, quinidine, quinine, oxaliplatin, rifampicin, sulfamethoxazole, trimethoprim, and vancomycin are probably the most frequently implicated (Curtis, 2014). The example of oxaliplatin is informative, as this can induce thrombocytopenia by both immune and nonimmune mechanisms. Thrombocytopenia is a significant problem for cancer patients being treated with this third-generation platinum drug as it occurs, for example, in more than 70% of patients with colorectal cancer receiving oxaliplatin. In most patients this effect is moderate in nature, but in 3% to 4% of patients it produces severe grade 3 to 4 thrombocytopenia causing life-threatening bleeding (Woo et al., 2015). The main cause of thrombocytopenia related to oxaliplatin use is myelosuppression, which represents asymptomatic thrombocytopenia. In some patients, hepatic sinusoid damage by oxaliplatin leads to portal hypertension and resultant splenic sequestration of platelets. Immune-mediated thrombocytopenia rarely occurs during oxaliplatin infusion but results in the severe life-threatening grade 3 to 4 thrombocytopenia that causes bleeding, hypersensitivity reactions, or hemolysis. These symptoms and thrombocytopenia occur suddenly after administration of oxaliplatin and can be treated by stopping oxaliplatin infusion. However, the rareness

of the immune-mediated effect sometimes makes it difficult to recognize (Woo et al., 2015).

Heparin-induced thrombocytopenia (HIT) represents another mechanism of immune-mediated platelet destruction (Evans and Gomes, 2017). This disorder is due to the development of antibodies that react with a multimolecular complex formed by the interaction between heparin and a protein, usually platelet factor 4 (PF 4) (Warkentin and Greinacher, 2004; Davoren and Aster, 2006). When the relative concentration of heparin to PF 4 is appropriate, formation of this complex is associated with exposure of a neoepitope on PF 4 (or another target protein) and development of an IgG response to the neoepitope. The IgG then binds to the PF 4–heparin complex to form an immune complex that binds to the platelet Fc receptor, FcγRIIa. Clustering of platelet FcγRIIa by the immune complex activates biochemical signaling pathways mediated by the cytoplasmic domain of FcγRIIa. This results in platelet activation and aggregation. During the process of platelet activation, platelet microparticles that promote thrombin generation are released. Consequently, HIT is associated with both thrombocytopenia and an increased risk of arterial and venous thrombosis. Other drug–antibody complexes (e.g., streptokinase–IgG) may trigger platelet activation and thrombocytopenia through a similar mechanism (Deckmyn et al., 1998; McRedmond et al., 2000).

Thrombotic thrombocytopenic purpura (TTP) is a rare and life-threatening thrombotic microangiopathy characterized by microangiopathic hemolytic anemia, severe thrombocytopenia, and organ ischemia linked to disseminated microvascular platelet rich-thrombi (Joly et al., 2017). TTP is specifically related to a severe deficiency in ADAMTS13 (a disintegrin and metalloprotease with thrombospondin type 1 repeats, member 13), the specific von Willebrand (vWF) factor-cleaving protease. ADAMTS13 deficiency is most frequently acquired via ADAMTS13 autoantibodies, but rarely, it is inherited via mutations of the *ADAMTS13* gene. The pathogenesis of TTP appears to be related to the ability of unusually large vWF multimers to activate platelets, even in the absence of significant vascular damage (Lian, 2005). Although these large multimers are normally secreted into blood by endothelial cells, they are rapidly processed into smaller multimers by ADAMTS13, which is present in plasma. Acquired TTP is associated with the development of an antibody that inhibits this protease, permitting the very large vWF multimers to persist in the circulation (Lian, 2005; Veyradier and Meyer, 2005). Consequently, these multimers bind to platelet GP Ib/IX/V and induce platelet activation and aggregation. The organ failure and hemolysis in TTP is due to the formation of platelet-rich microthrombi throughout the circulation. A recent review described the association of more than 70 drugs with TTP (Al-Nouri et al., 2015). In this systematic review, 22 drugs had evidence of a definite association with TTP, but only 3 of these accounted for the majority of cases reported; namely quinine, cyclosporine, and tacrolimus (Al-Nouri et al., 2015). In some cases, drug-induced TTP is related to development of antibodies to ADAMTS13, whereas in other cases it may be due to direct endothelial cell toxicity from the drug.

Hemolytic uremic syndrome (HUS) is a disorder characterized by clinical features similar to those of TTP, with microangiopathic hemolytic anemia, thrombocytopenia, and renal failure. HUS is usually categorized as typical, caused by Shiga toxin-producing *Escherichia coli* (STEC) infection, as atypical HUS (aHUS), usually caused by uncontrolled complement activation, or as secondary HUS with a coexisting disease (Jokiranta, 2017). Typical HUS (i.e., STEC-HUS) follows a gastrointestinal infection with STEC, whereas aHUS is associated primarily with mutations or autoantibodies leading to dysregulated complement activation. Among the 30% to 50% of patients with HUS who have no detectable complement defect, some have either impaired diacylglycerol kinase ε (DGKε) activity, cobalamin C deficiency, or plasminogen deficiency. Some have secondary HUS with a coexisting disease or trigger such as autoimmunity, transplantation, cancer, infection, certain drugs, or pregnancy. The common features in STEC-HUS, aHUS, and secondary HUS are simultaneous damage to endothelial cells, intravascular hemolysis, and activation of platelets leading to a procoagulative state, formation of microthrombi, and tissue damage (Jokiranta, 2017). Desmopressin, a vasopressin analog, is an example of nonimmune-mediated increased platelet destruction. It induces a two- to fivefold increase in the plasma concentration of vWF and factor VIII. It is commonly used in the treatment of patients with von Willebrand disease and other mild bleeding syndromes (Federici, 2008). Desmopressin has been associated with the development or accentuation of thrombocytopenia in some patients with type 2B von Willebrand disease. The thrombocytopenia in such cases is related to the release of an abnormal vWF from endothelial cells. The abnormal vWF has enhanced affinity for GP Ib/IX/V and the interaction of the vWF with its receptor leads to platelet clearance from the circulation (Mannucci, 1998).

Toxic Effects on Platelet Function Platelet function is dependent on the coordinated interaction of a number of biochemical response pathways. A variety of drugs and foods have been found to inhibit platelet function, either in vivo or in vitro (Abrams, 2006). Major drug groups that affect platelet function include nonsteroidal anti-inflammatory drugs, β-lactam-containing antibiotics, cardiovascular drugs, particularly β-blockers, psychotropic drugs, anesthetics, antihistamines, and some chemotherapeutic drugs. The effect of these drugs can vary between individuals, perhaps due to subclinical variations in underlying platelet function.

Xenobiotics may interfere with platelet function through a variety of mechanisms. Some drugs inhibit the phospholipase A_2/cyclooxygenase pathway and synthesis of thromboxane A_2 (e.g., nonsteroidal anti-inflammatory agents). Other drugs appear to interfere with the interaction between platelet agonists and their receptors (e.g., antibiotics, ticlopidine, clopidogrel). As the platelet response is dependent on a rapid increase in cytoplasmic calcium, any chemical that interferes with translocation of calcium may inhibit platelet function (e.g., calcium channel blockers). Occasionally, drug-induced antibodies will bind to a critical platelet receptor and inhibit its function. The functional defect induced by such antibodies may potentiate the bleeding risk associated with the xenobiotic-induced thrombocytopenia. In some cases, the mechanism of inhibition is not known.

Laboratory tests of platelet function, such as bleeding time, light transmission platelet aggregation, lumiaggregometry, impedance aggregometry on whole blood, and platelet activation investigated by flow cytometry, are traditionally utilized for diagnosing hemostatic disorders and managing patients with platelet and hemostatic defects (Paniccia et al., 2015). The effect of xenobiotics on platelet function can be studied in vivo with these methods, but several effects can also be used following in vitro exposure of platelets to the chemical of interest and/or its metabolites. The most common method of assessing platelet function is turbidimetric platelet aggregation using platelet-rich plasma, but several devices that are much simpler to use have recently become available (i.e., PFA-100, VerifyNow System, Multiplate Electrode Aggregometry [MEA], Paniccia et al., 2015).

Toxic Effects on Fibrin Clot Formation

Coagulation Fibrin clot formation is the result of sequential activation of a series of serine proteases that culminates in the formation of thrombin (Lane et al., 2005; Monroe and Hoffman, 2005).

Table 11-11

Conditions Associated with Abnormal Synthesis of Vitamin K–Dependent Coagulation Factors

Warfarin and analogs	Intravenous α-tocopherol
Rodenticides (e.g., brodifacoum)	Dietary deficiency Cholestyramine resin
Broad-spectrum antibiotics	Malabsorption syndromes
N-Methyl-thiotetrazole cephalosporins	

Thrombin is a multifunctional enzyme that converts fibrinogen to fibrin; activates factors V, VIII, XI, XIII, protein C, and platelets; and interacts with a variety of cells (e.g., leukocytes and endothelial cells), activating cellular signaling pathways (Lane et al., 2005).

The most common toxic effect of xenobiotics on fibrin clot formation are related to a decreased level of one or more of the critical proteins necessary for this process. The decrease in clotting factor activity may be due to decreased synthesis of the protein(s) or increased clearance from the circulation. Decreased synthesis is most often a reflection of hepatocellular damage or interference with vitamin K metabolism, as discussed below, whereas increased clearance is usually associated with the development of an antibody to a specific coagulation factor.

Decreased Synthesis of Coagulation Proteins The majority of proteins involved in the coagulation cascade are synthesized in the liver. Therefore, any chemical that impairs liver function may cause a decrease in production of coagulation factors. The common tests of the coagulation cascade, the prothrombin time (PT) and activated partial thromboplastin time (aPTT), may be used to screen for liver dysfunction and a decrease in clotting factors. These assays are often performed as part of the safety evaluation of a new chemical entity. The half-life of clotting factors in the circulation varies significantly, with factor VII having the shortest half-life (3 to 4 hours). Therefore, with acute toxicity (e.g., acetaminophen overdose), the effect on blood coagulation may be first seen as a decrease in the level of factor VII. Such a decrease would lead to prolongation of the PT with a normal aPTT. With a more chronic process, the PT, the aPTT, or both may be affected.

Factors II, VII, IX, and X are dependent on vitamin K for their complete synthesis (Stafford, 2005). Anything that interferes with vitamin K metabolism may lead to a deficiency of these factors and a bleeding tendency. This may occur with xenobiotics that interfere with absorption of vitamin K from the intestine or with chemicals that interfere with the reduction of vitamin K epoxide (Table 11-11). The combination of antibiotic therapy and limited oral intake is a common cause of acquired deficiency of vitamin K–dependent proteins among hospitalized patients (Chakraverty et al., 1996). The "super rodenticides" are another cause of acquired vitamin K deficiency (Chua and Friedenberg, 1998; Berry et al., 2000). These chemicals have a very prolonged half-life in vivo; thus, the coagulation defect may persist for weeks or months following exposure. Rodenticide exposure may occur accidentally, as part of a Munchausen syndrome, in association with a suicide attempt, or as part of a homicide attempt. At times it may be important to distinguish between a true vitamin K deficiency and interference with the reduction of vitamin K epoxide. This is most readily accomplished by measuring the level of vitamin K and vitamin K epoxide in serum or plasma. In the case of vitamin K deficiency, both vitamin K and vitamin K epoxide are decreased, whereas in the case of inhibition of vitamin K reduction, vitamin K epoxide is significantly increased. Specific rodenticides may be measured using HPLC techniques, but it is important to specify which active chemical (e.g., brodifacoum) should be measured, as the assays may not show cross-reactivity between chemicals.

Table 11-12

Relationship Between Xenobiotics and the Development of Specific Coagulation Factor Inhibitors

COAGULATION FACTOR	XENOBIOTIC
Thrombin	Topical bovine thrombin Fibrin glue
Factor V	Streptomycin Penicillin Gentamicin Cephalosporins Topical bovine thrombin
Factor VIII	Penicillin Ampicillin Chloramphenicol Phenytoin Methyldopa Nitrofurazone Phenylbutazone
Factor XIII	Isoniazid Procainamide Penicillin Phenytoin Practolol
von Willebrand factor	Ciprofloxacin Hydroxyethyl starch Valproic acid Griseofulvin Tetracycline Pesticides

Increased Clearance of Coagulation Factors Idiosyncratic reactions to xenobiotics include the formation of antibodies that react with coagulation proteins. These antibodies bind to the coagulation factor, forming an immune complex that is rapidly cleared from the circulation and resulting in deficiency of the factor. The antibody is often reversible over time if the initiating agent is withdrawn. However, during the acute phase, these patients may have life-threatening bleeding. The factors that are most often affected include factors VIII, V, and XIII, vWF, prothrombin, and thrombin (Table 11-12) (Lollar, 2004, 2005). Many of these antibodies inhibit the functional activity of the coagulation factor in addition to increasing the rate of clearance. Other antibodies have been demonstrated to have catalytic activity, resulting in proteolysis of the target coagulation factor (Ananyeva et al., 2004).

Lupus anticoagulants are antibodies that interfere with in vitro phospholipid-dependent coagulation reactions (Bertolaccini et al., 2004). Although it was once hypothesized that these antibodies were directed against phospholipid, it is now evident that lupus anticoagulants are directed against phospholipid-binding proteins, including prothrombin and β_2-glycoprotein 1. These antibodies usually do not cause a deficiency of any specific coagulation factor. However,

in vivo, these antibodies can potentiate procoagulant mechanisms and interfere with the protein C system. Consequently, these antibodies have been associated with an increased risk of thrombosis (Bertolaccini et al., 2004). The development of lupus anticoagulants has been seen in association with a variety of medications, including procainamide, chlorpromazine, and hydralazine.

Toxicology of Chemicals Used to Modulate Hemostasis

Patients with bleeding or thrombotic problems are commonly encountered in clinical practice. A variety of agents are available to treat such patients, ranging from recombinant hemostatic proteins to chemical entities that modulate the activity of the coagulation system. The major toxicologic reactions to plasma-derived products are infectious diseases (e.g., hepatitis C) and allergic reactions, which can be severe. The use of some products, such as activated concentrates of vitamin K–dependent proteins (e.g., Autoplex and FEIBA), has been associated with the development of disseminated intravascular coagulation and/or thrombosis in some patients (Mannucci, 1998).

Oral Anticoagulants Oral anticoagulants (warfarin) interfere with vitamin K metabolism by preventing the reduction of vitamin K epoxide, resulting in a functional deficiency of reduced vitamin K (Ansell et al., 2004). These drugs are widely used for prophylaxis and therapy of venous and arterial thrombosis. The therapeutic window for oral anticoagulants is relatively narrow, and there is considerable interindividual variation in the response to a given dose. A number of factors, including concurrent medications and genetics, affect the individual response to oral anticoagulants (Ansell et al., 2004; D'Andrea et al., 2005; Rojas et al., 2005). For these reasons, therapy with these drugs must be routinely monitored to maximize both safety and efficacy. This is routinely performed with the PT, with results expressed in terms of the international normalized ratio (INR).

A number of xenobiotics, including foods, have been found to affect the response to oral anticoagulants (Ansell et al., 2004). Perhaps the most common mechanism for interference with oral anticoagulants is mediated by inhibition of CYP2C9 (Rojas et al., 2005). Other mechanisms of interference include induction of CYP2C9, which tends to diminish the effect of warfarin by shortening its half-life; interference with absorption of warfarin from the gastrointestinal tract; displacement of warfarin from albumin in plasma, which temporarily increases the bioavailability of warfarin until equilibrium is reestablished; diminished vitamin K availability, due to either dietary deficiency or interference with the absorption of this lipid-soluble vitamin; and inhibition of the reduction of vitamin K epoxide, which potentiates the effect of oral anticoagulants.

Just as other drugs interfere with the action of oral anticoagulants, administration of oral anticoagulants may affect the activity of other medications, particularly those that are metabolized by CYP2C9. Dicumarol administration prolongs the half-life of chlorpropamide and phenytoin, resulting in hypoglycemia in the case of chlorpropamide and an increased plasma drug concentration in the case of phenytoin. Bis-hydroxycoumarin, but not warfarin, potentiates the activity of tolbutamide, resulting in enhanced hypoglycemia (Harder and Thurmann, 1996).

Oral anticoagulants have been associated with the development of warfarin-induced skin necrosis (Ansell et al., 2004). This disorder is due to the development of extensive microvascular thrombosis in the affected skin. This uncommon toxic effect is thought to be related to a rapid drop in protein C following administration of the drug, resulting in impaired protein C function. The risk of developing warfarin-induced skin necrosis increases with the dose of warfarin used to initiate therapy, particularly when the initial dose exceeds 10 mg per day; this is one of the reasons that loading doses of warfarin are no longer recommended.

Vitamin K is necessary for the synthesis of proteins other than the coagulation-related factors, including osteocalcin, a major component of bone. Perhaps because of this, long-term administration of warfarin has been associated with bone demineralization (Ansell et al., 2004; Stafford, 2005). This effect can be important in patients with borderline bone density. Administration of warfarin during pregnancy, particularly the first 12 weeks of pregnancy, is associated with congenital anomalies in 25% to 30% of exposed infants (Bates et al., 2004). Many of the anomalies are related to abnormal bone formation. It is thought that warfarin may interfere with synthesis of proteins critical for normal structural development.

The last decade has seen development and increasing clinical use of the direct oral anticoagulants (DOACs), orally bioavailable direct inhibitors of either coagulation factor Xa (e.g., rivaroxaban, apixaban), or thrombin (i.e., dabigatran). As with any anticoagulant therapy, bleeding risk exists, although these newer agents are anticipated to begin to replace warfarin (Crowther, 2017). The DOACs do not require routine monitoring like warfarin, and reversal strategies are FDA-approved or emerging, depending on the drug (Pollack et al., 2015; Connolly et al., 2016). Because these new agents work by directly inhibiting specific coagulation proteases, and not by altering vitamin K levels, adverse effects related to changes in vitamin K are limited, although these newer drugs are not without potential for drug–drug interaction (Di Minno et al., 2017).

Heparin Heparin is a widely used anticoagulant for both prophylaxis and therapy of acute venous thromboembolism (Hirsh and Raschke, 2004). In many hospitals, the majority of patients are exposed to this potent anticoagulant at some point during their hospitalization. The major complication associated with heparin therapy is bleeding, a direct manifestation of its anticoagulant activity. The risk of bleeding is related to the intensity of therapy, the patient's body mass and underlying condition, and the presence of other hemostatic defects (e.g., thrombocytopenia).

As discussed in the section "Toxic Effects on Platelets," heparin administration is also associated with the development of heparin-induced thrombocytopenia (HIT). For unknown reasons, this complication occurs more frequently with heparin derived from bovine sources than with that derived from porcine sources. The incidence of HIT is also significantly higher in patients receiving unfractionated heparin than it is in patients receiving low-molecular-weight heparin (Warkentin and Greinacher, 2004; Davoren and Aster, 2006).

Long-term administration of heparin is associated with an increased risk of clinically significant osteoporosis (Hirsh and Raschke, 2004; Dinwoodey and Ansell, 2006). The mechanism underlying the development of osteoporosis in these patients is not known. Patients may suffer from spontaneous vertebral fractures and demineralization of long bones of the arms and legs. The risk of osteoporosis may be less with low-molecular-weight heparin as compared with that with unfractionated heparin.

Heparin administration may also cause a transient rise in serum transaminases, suggesting significant liver dysfunction (Guevara et al., 1993). However, the rise is rapidly reversible on discontinuation of heparin and may reverse even before heparin is discontinued. The elevation of serum transaminases has not been associated with chronic liver dysfunction. The mechanism of heparin-induced increase in transaminases is not known.

In 2008, serious injuries and deaths were associated with the use of heparin originating in China. It was determined that certain

sources of heparin were contaminated with oversulfated chondroitin sulfate (OSCS). The presence of OSCS is believed to be responsible for the observed severe allergic reactions, gastrointestinal disturbances, and hypotension (Blossom et al., 2008).

Fibrinolytic Drugs Fibrinolytic drugs are used in the treatment of acute thromboembolic disease with the goal of dissolving the pathogenic thrombus (Collen and Lijnen, 2005). Each of these drugs works by converting plasminogen, an inactive zymogen, to plasmin, an active proteolytic enzyme. Plasmin is normally tightly regulated and is not freely present in the circulation. However, administration of fibrinolytic drugs regularly results in the generation of free plasmin leading to systemic fibrin(ogen)olysis. The toxicology of the fibrinolytic drugs can be divided into toxic effects of systemic plasmin activation and toxic effects of the activators themselves.

Systemic fibrinolysis is associated with the development of a complex coagulopathy characterized by a decrease in fibrinogen, factors V and VIII, and α_2-antiplasmin; an increase in circulating fibrin split products; degradation of platelet GP Ib/IX/V and IIb/IIIa; degradation of endothelial cell glycoproteins; degradation of fibronectin and thrombospondin; and prolongation of the PT, aPTT, and thrombin time (Hajjar, 2006). All of these effects potentiate the risk of bleeding. Anatomic locations that are frequently involved in bleeding complications include the cerebral circulation and sites of recent vascular access. As systemic plasmin can lyse physiologic as well as pathologic thrombi, reactivation of bleeding from sites of vascular access is not uncommon. Platelet inhibitors and heparin are commonly used in conjunction with fibrinolytic therapy to prevent recurrent thrombosis. As one might expect, the concurrent use of anticoagulants with systemic fibrinolysis may contribute to the risk of bleeding (Menon et al., 2004).

Another complication associated with fibrinolysis is recurrent thrombosis at the site of pathologic thrombosis. While rethrombosis may be related to underlying damage to the vascular wall, there is some evidence that fibrinolytic therapy may contribute to this process. For example, plasmin, in appropriate concentrations, can actually induce platelet activation (McRedmond et al., 2000). This process may be mediated by plasmin or streptokinase/plasminogen cleavage of the platelet thrombin receptor (protease activated receptor-1). Cleavage of the receptor is associated with activation of the platelet biochemical signaling pathways. There is sufficient "cross-talk" between the fibrinolytic system and the contact system of coagulation that one could also anticipate increased thrombin generation occurring as a result of fibrinolytic therapy (Schmaier et al., 1999).

Streptokinase is a protein derived from group C β-hemolytic streptococci and is antigenic in humans. Antibody formation to streptokinase occurs commonly in association with streptococcal infections as well as exposure to streptokinase. Acute allergic reactions may occur in 1% to 5% of patients exposed to streptokinase, and these allergic reactions may consist of minor symptoms such as hives and fever as well as major, life-threatening anaphylactic reactions. In addition, delayed hypersensitivity reactions associated with severe morbidity may occur (Siebert et al., 1992; Curzen et al., 1998). Allergic reactions also occur with other fibrinolytic drugs containing streptokinase (e.g., anisoylated plasminogen–streptokinase complex) or streptokinase-derived peptides. The immune complex formed by IgG and streptokinase is capable of binding to and clustering platelet FcγRIIa, initiating platelet activation and aggregation (McRedmond et al., 2000).

Urokinase and recombinant tissue plasminogen activator (t-PA) are generally not associated with allergic reactions. However, work is progressing on a number of genetically engineered forms of t-PA. Whether or not such mutant forms of t-PA are immunogenic has not been firmly established (Collen and Lijnen, 2005).

Inhibitors of Fibrinolysis Inhibitors of fibrinolysis are commonly used to control bleeding in patients with congenital abnormalities of hemostasis, such as von Willebrand disease. Tranexamic acid and ε-aminocaproic acid are small molecules that block the binding of plasminogen and plasmin to fibrin and other substrate proteins through interaction with lysine binding sites on plasmin(ogen). Although relatively well tolerated, there is some evidence that administration of these chemicals may increase the risk of thrombosis due to the inhibition of the fibrinolytic system (Mannucci, 1998). In a single case, intravenous infusion of ε-aminocaproic acid in a patient with chronic renal failure was associated with acute hyperkalemia (Perazella and Biswas, 1999).

Aprotinin is a naturally occurring polypeptide inhibitor of serine proteases. It is usually derived from bovine material and consequently is immunogenic when administered to humans. Aprotinin is given by intravenous infusion, as it is inactive when given orally. Allergic reactions in response to aprotinin have been reported, ranging from minor cutaneous manifestations to anaphylactic reactions (Peters and Noble, 1999). A more recent observational study compared clinical outcomes after cardiac surgery performed with aprotinin, tranexamic acid, or ε-aminocaproic acid with outcomes after cardiac surgery without an inhibitor of fibrinolysis (Mangano et al., 2006). In this study, use of antifibrinolytics was associated with decreased blood loss. However, use of aprotinin was associated with a significant increase in end-organ damage, including renal, cardiac, and cerebral events. The design and results of this study have been questioned, with calls for prospective randomized comparator studies (Sedrakyan et al., 2006). The results also point out the intricate balance within the hemostatic system and the potential for problems when modulating the activity of one portion of this system.

HEMATOTOXICITY TESTS

Assessing the risk that exposure to new drugs, chemical products, and other agents poses to humans—in terms of significant toxic effects on hematopoiesis and the functional integrity of blood cells and hemostatic mechanisms—can be logistically and intellectually challenging. This is due in part to the complexity of hematopoiesis and the range of important tasks that these components perform, as previously discussed.

Animal Studies

Conventional hematotoxicity testing in animals assesses peripheral blood cell parameters (complete blood counts) and histopathology of bone marrow and other hematopoietic tissues. Specific tests used vary with the phase or objective of the evaluation (acute, subacute, chronic), the intended use of the chemical, and what is understood or suspected regarding the toxicologic profile of the xenobiotic. Ideally, the studies in aggregate should provide information on the effects of single- and multiple-dose exposure on erythrocyte parameters (RBC, Hbg, PCV, MCV, MCHC), leukocyte parameters (WBC and absolute differential counts), thrombocyte counts, screening coagulation tests (PT, aPTT), peripheral blood cell morphology, and bone marrow cytologic and histologic features (Bloom, 1993; Weingand et al., 1996; Lund, 2000). Best practices for evaluation of bone marrow toxicity in nonclinical studies were developed through a joint effort of the American Society for Veterinary Clinical Pathology and the Society of Toxicologic Pathology (Bone Marrow Working Group) (Reagan et al., 2011). Cytological or flow cytometric evaluation of bone marrow is useful

Table 11-13

Examples of Problem-Driven Tests Used to Characterize Hematologic Observations in Preclinical Toxicology

Flow cytometry (see text)
Heinz body preparation
Cell-associated antibody assays (erythrocyte, platelet, neutrophil)
Erythrocyte osmotic fragility test
Erythrokinetic/ferrokinetic analyses
Cytochemical/histochemical staining
Electron microscopy
In vitro hematopoietic clonogenic assays
Platelet aggregation
Plasma fibrinogen concentration
Clotting factor assays
Thrombin time
Bleeding time

to characterize effects on different hematopoietic lineages or stem or progenitor cells. Examples of additional tests that can be used to better characterize findings from initial screening efforts or to more fully explore a class-specific effect or other hematotoxicologic potential of concern (Bloom, 1993) are listed in Table 11-13.

Important considerations for animal toxicity studies include the selection of the appropriate animal model. Rats and mice are commonly used species and both have been well characterized hematologically (Valli and McGrath, 1997; Moore, 2000a, 2000b). However, their small size precludes serial sampling of blood and bone marrow. Larger species, such as the dog and monkey, enable serial sampling and are hematologically more similar to humans, as regards hematopoiesis and blood cell kinetics, which in the monkey extends to immunohematologic features (Shifrine and Wilson, 1980; Ladiges et al., 1990). However, interanimal hematologic variability is an issue in monkeys, particularly in wild-caught primates.

Interspecies differences limit the relevance of animal studies to human hematotoxicity. Conventional peripheral blood cell parameters in animals have limited predictive value for human hematotoxicity. Animal studies may be even less predictive for human recombinant proteins, monoclonal antibodies, and targets that are specific to human tissue and disorders, or for idiosyncratic iatrogenic disease in humans, such as aplastic anemia and agranulocytosis. Mice are not relevant for testing toxicity of infectious agents with exclusively human or primate hosts.

Interspecies differences in sensitivity of bone marrow cells to anticancer drugs were previously reported (Erickson-Miller et al., 1997; Pessina et al., 2003; Masubuchi, 2006). In order to improve the relevance of the mouse model for human hematotoxicity, a humanized bone marrow xenograft mouse model was developed (Cai et al., 2011). It was validated with a temozolomide-based regimen that is known to have dose limiting toxicity in the clinic. Flow cytometric analysis indicated that human bone marrow cells were more sensitive to treatment than mouse bone marrow cells and that all lineages were affected. This model enables the screening of the response of bone marrow cells in their microenvironment.

Most of IARC's Group 1 leukemia- and lymphoma-inducing agents were reported previously to be carcinogenic in rodent bioassays (Eastmond, 1997), suggesting a good correlation between animal and humans. However, many of the leukemias or lymphomas induced in mice were T-cell leukemias or lymphomas, rather than AML, the predominant human form. The difference in tumor types may be related to species differences in hematopoiesis and/or immune surveillance (Eastmond, 1997).

The strains of animals widely used in animal studies are genetically similar and do not approximate human genetic variability for gene by environment studies. Genetically diverse mouse models such as Collaborative Cross strains (Threadgill et al., 2011) and Diversity Outbred mice (Churchill et al., 2012) have been developed to address this. They enable the examination of effects of environmental exposures against variable genetic backgrounds. For example, two sulfotransferase genes were identified as candidate susceptibility genes related to benzene-induced genotoxicity in bone marrow cells using Diversity Outbred mice (French et al., 2015). However, there are no human homologs of these sulfotransferase genes in humans, indicating that findings in rodents must be interpreted cautiously.

Human Population Studies

Treatment with drugs and therapeutics can lead to *idiosyncratic reactions* that cause toxicity in a small number of susceptible individuals (Patton and Duffull, 1994; Dieckhaus et al., 2002) and may include aplastic anemia, thrombocytopenia, hemolysis, and leukopenia, which may or may not be immune-mediated (Salama et al., 1989). Examples of iatrogenic blood dyscrasias detected through postmarketing surveillance include the hemolysis and thrombocytopenia associated with the antibiotic temafloxacin, the aplastic anemia linked to the antiepileptic felbamate, the hemolysis caused by the antidepressant nomifensine, and the agranulocytosis associated with the antiarrhythmic aprindine.

The WHO has established criteria for grading hematotoxicity (WHO, 1979), which are summarized in Table 11-14. These have been particularly useful in establishing and communicating treatment strategies and guidelines for chemicals known to suppress hematopoiesis (cytoreductive oncolytic, immunosuppressive, and antiviral agents, etc.) and for which this limiting toxicity is used to establish maximum tolerated doses for individual patients.

Idiosyncratic reactions may be detected in Phase III clinical trials or through postmarketing surveillance, such as the MedWatch program introduced by the FDA in 1993 (Szarfman et al., 1997). Global adverse event data, including serious hematotoxicity, are provided to the WHO; this information is compiled by a computer-based recording system employing WHO terminology and system and organ classifications for adverse reactions (Edwards et al., 1990). Data mining techniques enable the quantitative analysis of large public databases (Szarfman et al., 2002; Hopstadius et al., 2008) or pharmaceutical company databases (Egberts et al., 2002; Lehman et al., 2007) for detection of drug-adverse event relationships. These approaches can detect concealed associations (Lehman et al., 2007) and are recognized as important tools in pharmacovigilance (Almenoff et al., 2005; Hauben et al., 2005).

In Vitro Bone Marrow Assays

In vitro methods for assessing potential hematotoxicity are faster and less expensive than in vivo studies, while providing mechanistic data. Suppressive effects on HSC can be assessed using short-term clonogenic assays including burst-forming-unit erythroid (BFU-E), colony-forming-unit erythroid (CFU-E), colony-forming-unit granulocyte/monocyte (CFU-GM), colony-forming-unit megakaryocyte (CFU-MK), and colony-forming-unit granulocyte, erythroid, megakaryocyte, monocyte (CFU-GEMM), which have been developed for several laboratory animal species (Pessina et al.,

Table 11-14

WHO Grading Criteria for Subacute and Acute Hematotoxicity

HEMATOLOGIC PARAMETERS (ADULTS)	GRADE 0	GRADE 1	GRADE 2	GRADE 3	GRADE 4
Hemoglobin (g/dL) (nmol/L)	11.0 (6.8)	9.5–10.5 (6.5–6.7)	8.0–9.4 (4.95–5.8)	6.5–7.9 (4.0–4.9)	6.5 (4.0)
Leukocytes (1000/μL)	4.0	3.0–3.9	2.0–2.9	2.0–1.9	1.0
Granulocytes (1000/μL)	2.0	1.5–1.9	1.0–1.4	0.5–0.9	0.5
Platelets (1000/μL)	100	75–99	50–74	25–49	<25
Hemorrhage, blood loss	None	Petechiae	Mild	Gross	Debilitating

SOURCE: Data from WHO (1979).

2005). These assays enable the examination of tightly controlled exposure concentrations and durations effects on the myeloid, erythroid, and megakaryocytic lineages.

In vitro clonogenic assays have a number of advantages. Most important is the ability to test human hematopoietic cells directly in a preclinical setting, thus obviating extrapolation considerations. In vitro assays can be used to test combinations of chemicals as well as their metabolites and effects of serum and other cell components, such as lymphocytes (Pisciotta, 1997). Adaptations to incorporate metabolic activation have been developed such as incorporation of liver microsomes and cofactors as a metabolic system into the CFU-GM assay protocol (Dal Negro et al., 2006). A coculture model utilizing HepG2 liver spheroids as a source of metabolic enzymes and mesenchymal cells was used to assess mesenchymal stem cell (MSC) damage and was validated using chemotherapeutic agents, both prodrugs and active drugs (May et al., 2012). When used in a preclinical setting in combination with in vivo testing, the predictive value of these assays is enhanced, for example, the in vitro component has been used for therapeutic index-based screening to identify less myelosuppressive analogs of anticancer and antiviral drugs, structure–toxicity relationships, and new-drug lead candidates (Deldar and Stevens, 1993; Parchment et al., 1993; Pessina et al., 2003).

In vitro clonogenic assays in risk assessment have been useful for making practical interspecies comparisons regarding sensitivity to a particular agent or group of drugs or chemicals. Comparisons to the sensitivity of human cells can be made that have implications for the relative predictive value of various animal models for hematotoxicity in humans. Examples include the resistance of murine CFU-GM to the anticancer drug topotecan relative to that of the canine and human cells (Deldar and Stevens, 1993). This is consistent with the early observations of Marsh—that the dog is a particularly predictive model for the myelosuppression associated with anticancer drugs in humans (Marsh, 1985). Thus, while some chemicals show comparable suppressive activity across species lines (doxorubicin, pyrazoloacridine, hepsulfan, cyclopentenyl cytosine), others, such as camptothecins, carboxyamidotriazole, and fostriecin, show differences of as much as three log concentrations (Horikoshi and Murphy, 1982; Du et al., 1991; Reagan et al., 1993). Using CFU-GM-, BFU-E-, and CFU-E-clonogenic assays, aflatoxins B1 and M1 were reported to induce dose-dependent toxic effects on human and mouse stem cells, with higher sensitivity in human cells, and had greater impacts on myeloid and the immature erythroid lineages in both species (Roda et al., 2010).

One of the limitations of the assays is the low-throughput capacity. While the most commonly applied clonogenic techniques still employ viscous or semisolid matrices and culture supplements that promote differentiation of the hematopoietic cells (Erickson-Miller et al., 1997; McMullin et al., 1998), some newer techniques use liquid culture. In the automated non-clonogenic fluorometric microculture cytotoxicity assay (FMCA), human CD34 cells are incubated in 384-well microplates with drugs in liquid culture, supplemented with GM-stimulating cytokines, after which cell survival is assessed (Haglund et al., 2010). Extensive validation with known myelotoxic drugs found similar 50% inhibitory concentrations (IC(50)) after 7 days of culture as standard proposed FMCA-GM assays. Other assays measure intracellular ATP as a measure of proliferation. For example, HALO® (Hemotoxicity Assays via Luminescence Output) is an ATP-based bioluminescence assay that is conducted in 96-well culture plates and is completed in half the time of the manual clonogenic assay (Rich and Hall, 2005). Fourteen different lymphohematopoietic populations from three different tissues (peripheral blood, bone marrow, and cord blood) and from five different species (human, nonhuman primate, dog, rat, and mouse) can be assayed. HALO® has been extensively used for screening and studying various compounds (Rich and Hall, 2005; Parent-Massin et al., 2010). Platforms that enable the liquid culture of HSC/HPC can be used in conjunction with multiple other assays to understand mechanism of action, including mitochondrial dysfunction, genotoxicity (micronucleus assay), proliferation, differentiation, oxidative stress, cytokine release, chemotaxis/migration, oxidative stress, apoptosis, etc. Other commercially available products considerably improve the throughput of clonogenic assays (Yadav et al., 2016).

Because myelotoxicity, and particularly suppression of granulopoiesis, is a major limitation in administering anticancer drugs, and is often used to determine the optimal dose, the clonogenic assay for CFU-GM has received the most attention as a preclinical tool for predicting this response. It is the only assay that has been validated by an international study supported by the European Centre for Validation of Alternative Methods (ECVAM) (Pessina et al., 2003). Analytical validation was completed for the human and mouse assays, and a predictive model was developed to calculate the maximum tolerated dose (MTD) in humans using data from the mouse assay that is adjusted for the established interspecies variation (Pessina et al., 2001). The model was applied in an international blind trial to 20 drugs that included 14 antineoplastic drugs, the antiviral drugs zidovudine and acyclovir, and the pesticide lindane (Pessina et al., 2003). It predicted the MTD for all 20 chemicals, although extrapolation on the regression curve out of the range of the actual drug doses tested was required to derive the IC90 for 10 of these drugs. Since then, the Scientific Advisory Committee of the ECVAM endorsed the CFU-GM assay for predicting acute neutropenia in humans as a substitute to using a second species, such as the dog, for this purpose (24th meeting at ECVAM of the ECVAM Scientific Advisory Committee, European Commission, March 2006). Subsequent studies have confirmed the predictive value of this assay in both anticancer drugs (Masubuchi, 2006)

and nononcology candidate drugs (Horn et al., 2008). The latter study illustrates the species specificity encountered and the importance of integrating the in vivo and in vitro approaches required to fully characterize the hematotoxicity observed in preclinical safety assessment today.

While this discussion has focused on in vitro hematopoietic clonogenic assays in the context of risk assessment, these assays have also proven to be extraordinarily useful tools for investigating mechanisms of toxic cytopenia in humans (Deldar, 1994). Parchment and Murphy (1997) review the application of these to four categories of hematologic toxicity observed clinically: (1) the reversible cytopenia following acute exposure to a cytotoxic or cytostatic chemical; (2) the permanent loss in the production of a mature blood cell type(s); (3) cytosis, or the dramatic increase in blood cell counts following single or repeated toxicant exposure; and (4) the progressive loss of one or more blood cell lineages during chronic exposure to a toxicant. In all these circumstances, in vitro and ex vivo hematopoietic clonogenic assays have proven useful in understanding the mechanism(s) of these toxic effects and formulating strategies for risk management and treatment. Clonogenic assays have been used to show the effects of iron overload on hematopoietic progenitor cells in myelodysplastic syndrome (MDS) patients; proliferation of BFU-E but not CFU-GM was suppressed (Hartmann et al., 2013). Clonogenic assays have shown that bone marrow-derived HSC/HPC that are present in circulating peripheral blood are suppressed in human populations exposed to benzene and formaldehyde (Lan et al., 2004; Zhang et al., 2010c). Further, chromosomal abnormalities were detected in the resulting colonies (Zhang et al., 2010c, 2012). As circulating HSC/HPC originate in bone marrow, these assays allow the indirect assessment of bone marrow-derived cells in healthy, human subjects without using invasive sampling methods.

Emerging Technologies

Toxicogenomics Toxicogenomics involves the assessment by omic technologies of the genome, transcriptome, epigenome, proteome, and metabolome, of animals, people, or in vitro models that have been exposed to toxic agents. For example, analysis of the transcriptome by microarray, and more recently by next-generation sequencing (NGS), in the peripheral blood cells of benzene-exposed factory workers has identified potential biomarkers of exposure and early effect and mechanisms of action, even at levels below the occupational exposure limit (McHale et al., 2016). NGS revealed that benzene altered the expression of miRNAs related to hematopoiesis and hematological malignancies in HSC/HPC of exposed mice (Wei et al., 2015). Genomics studies using highly sensitive, error-corrected NGS methodologies detected low-frequency, leukemia-related mutations in the peripheral blood of individuals after treatment with cytotoxic chemotherapeutic drugs for a primary malignancy, up to 12 years before the diagnosis of therapy-related AML or therapy-related MDS (Wong et al., 2015; Young et al., 2015). Activity-based protein profiling or chemoproteomics can map targets of toxicants and delineate toxicological mechanisms (Ford et al., 2017).

Application of toxicogenomics in exposed human populations can inform risk assessment by elucidating mechanisms of action underlying exposure-related disease, identifying susceptible individuals, and revealing responses at low doses (McHale et al., 2010; Zhang et al., 2010b; McHale et al., 2012). Robust experimental design incorporating precise, individual exposure measurements, adequate power, relevant phenotypic endpoints, and range of exposure levels is necessary (McHale et al., 2016). Integrative omic analysis of various data types can provide more detailed pathway and network information, identify more robust biomarkers, and elucidate mechanisms of toxicity and disease, thus aiding risk characterization (Gohlke et al., 2009; Enfield et al., 2012; Shivarov and Bullinger, 2014; Nardini et al., 2015; van Breda et al., 2015). As more studies are performed and incorporated into databases such as the Comparative Toxicogenomics Database (CTD) and Chemical Effects in Biological Systems (CEBS), data can be mined for classification of newly tested chemicals (hazard identification), and, for investigating the dose–response, inter-relationship among genes, environment, and disease in a systems biology approach (risk characterization). For example, CTD pathway data was used to discriminate chemical leukemogens from non-leukemogens (Thomas et al., 2012).

3D Bone Marrow Niche Models Research groups have attempted to develop 3D models of the bone marrow niche using biomimetic materials, such as collagen microspheres, hydrogels, decellularized extracellular matrix extracts, and synthetic polyacrylates, as scaffolds (Kim et al., 2015; Dhami et al., 2016; Xu et al., 2016; Houshmand et al., 2017). Although progress has been made, key challenges remain in replicating the complex interactions between HSCs and marrow microenvironments and precisely controlling the biochemical and physical niches that are critical in supporting hematopoiesis.

chapter 12

Toxic Responses of the Immune System

Barbara L.F. Kaplan, Courtney E.W. Sulentic, Helen G. Haggerty, Michael P. Holsapple, and Norbert E. Kaminski

Introduction

The Immune System

- Innate Immunity
  - *Cellular Components: Neutrophils, Macrophages, Dendritic Cells, Natural Killer Cells, NKT Cells, γδ T Cells, and B-1 B Cells*
  - *Soluble Components: Acute-Phase Proteins, Granzyme, Perforin, and Complement*
- Antigen Recognition
  - *Antigen*
  - *Antibodies*
  - *Antigen Processing*
- Acquired (Adaptive) Immunity
  - *Cellular Components: Antigen-Presenting Cells, T Cells, and B Cells*
  - *Humoral and Cell-Mediated Immunity*
- Inflammation
  - *Cellular Components: Macrophages, Neutrophils, ILCs, and T Cells*
- Immune-Mediated Disease
  - *Hypersensitivity*
  - *Autoimmunity*
- Developmental Immunology
- Neuroendocrine Immunology

Assessment of Immunologic Integrity

- General Assessment
- Functional Assessment
  - *Innate Immunity*
  - *Acquired Immunity: Humoral*
  - *Acquired Immunity: Cell-Mediated*
  - *Flow Cytometric Analysis*
  - *Measurements of Cytokines and Cytokine Profiling*
  - *Cytokine Release Assays*
  - *Host Resistance Assays*
  - *Assessment of Developmental Immunotoxicology*
  - *Assessment of Hypersensitivity Responses*
  - *Assessment of Autoimmune Responses*
- Molecular Biology Approaches to Immunotoxicology
- Mechanistic Approaches to Immunotoxicology
  - *Identification of the Cell Type or Type(s) Targeted*
  - *Determination of Whether Immunotoxicity Is Mediated by the Parent or by a Metabolite of the Parent Compound*
  - *Determination of Whether the Effects Are Mediated Directly or Indirectly by the Xenobiotic or a Metabolite of the Xenobiotic*
  - *Elucidation of the Molecular Mechanism*
  - *Cell Line Models in Immunotoxicology*
  - *Animal Models: Transgenic, Knockout, and Humanized/SCID*
- Approaches to the Assessment of Human Immunotoxicity
- Regulatory Approaches to the Assessment of Immunotoxicity
  - *The National Toxicology Program Tier Approach*
  - *Historical Perspective on Regulatory Guidance in Immunotoxicology*
  - *Recent Advances in Regulatory Guidance on Immunotoxicology*

Immune Modulation by Xenobiotics

- Halogenated Aromatic Hydrocarbons
  - *Polychlorinated Dibenzodioxins*
  - *Polychlorinated Dibenzofurans and Polychlorinated Biphenyls*
  - *Polybrominated Biphenyls*
  - *Polycyclic Aromatic Hydrocarbons*
- Pesticides
  - *Organophosphates*
  - *Organochlorines*
  - *Organotins*
  - *Carbamates*
  - *Atrazine*
- Metals
  - *Lead*
  - *Arsenic*
  - *Mercury*
  - *Cadmium*
- Solvents and Related Chemicals
  - *Aromatic Hydrocarbons*
  - *Haloalkanes and Haloalkenes*
  - *Nitrosamines*
- Mycotoxins
- Natural and Synthetic Hormones
  - *Estrogens*
  - *Androgens*
  - *Glucocorticoids*
- Drugs of Abuse
  - *Cannabinoids*
  - *Opioids*
  - *Cocaine*
  - *Methamphetamine*
  - *Ethanol*
- Ultraviolet Radiation
- Therapeutic Drugs
  - *Anti-inflammatory Drugs*
  - *Immunosuppressive Agents*
  - *AIDS Therapeutics*

Xenobiotic-Induced Hypersensitivity and Autoimmunity

- Hypersensitivity
  - *Polyisocyanates*
  - *Acid Anhydrides*
  - *Metals*
  - *Latex*
  - *Food and Genetically Modified Organisms*
  - *Formaldehyde*
  - *Inhaled Substances*
  - *Therapeutic Drugs*
- Autoimmunity
  - *Vinyl Chloride and Organic Solvents*
  - *Mercury*
  - *Silica*
  - *Hexachlorobenzene*
  - *Therapeutic Drugs*

Immunotoxicity of Biologics

New Frontiers and Challenges in Immunotoxicology

Acknowledgments

References

INTRODUCTION

Immunotoxicology can be most simply defined as the study of adverse effects on the immune system resulting from occupational, inadvertent, or therapeutic exposure to drugs, environmental chemicals, and, in some instances, biological materials. Studies in animals and humans have indicated that the immune system is comprised of potential target organs, and that damage to this system can be associated with morbidity and even mortality. Indeed, in some instances, the immune system can be compromised (decreased lymphoid cellularity, alterations in lymphocyte subpopulations, decreased host resistance, altered specific immune function responses) in the absence of observed toxicity in other organ systems. These studies coupled with tremendous advances made in immunology and molecular biology have led to a steady and exponential growth in our understanding of immunotoxicology during the past 40 years. Recognition by regulatory agencies that the immune system is an important, as well as sensitive, target organ for chemical- and drug-induced toxicity is another indication of the growth of this subdiscipline of toxicology. With the availability of sensitive, reproducible, and predictive tests, it is now apparent that the inclusion of immunotoxicity testing represents a significant adjunct to routine safety evaluations for therapeutics, biologics, and chemicals now in development.

Understanding the impact of toxic responses on the immune system requires an appreciation of its role, which may be stated succinctly as the preservation of integrity. It is a series of delicately balanced, complex, multicellular, and physiologic mechanisms that allow an individual to distinguish foreign material (i.e., "nonself") from "self," and to neutralize, eliminate, and/or coexist with the foreign matter. One definition of nonself is essentially anything other than that encoded in one's own germline genome (Nathan, 2006). Examples of self are all the tissues, organs, and cells of the body. Examples of nonself include a variety of opportunistic pathogens, such as bacteria and viruses, and transformed cells or tissues (i.e., tumors). Nonself might also include drugs, xenografts, or allergens, such as pollen. The immune system is characterized by a virtually infinite repertoire of specificities, highly specialized effectors, complex regulatory mechanisms, and an ability to travel throughout the body. The great complexity of the mammalian immune system is an indication of the importance, as well as the difficulty, of its role. If the immune system fails to recognize as nonself an infectious entity or neoantigens expressed by a newly arisen tumor, then the host is in danger of rapidly succumbing to the unopposed invasion. This aspect of immune competence is the reason why the immune system is often synonymous with "host defense." Alternatively, if some integral bodily tissue is not identified as self, then the immune system is capable of turning its considerable defensive capabilities against that tissue, and elicitation of autoimmune disease may ensue. This aspect of immune competence emphasizes the tremendous destructive potential that is associated with the host defense mechanisms of the immune system. The cost to the host of these mistakes, made in either direction, may be quite high. The fact that mistakes can occur in either direction is an indication that immunotoxicology should be considered as a continuum (Fig. 12-1). At the center of the concept of the continuum is the recognition that immune responses in the normal human population can vary by more than two standard deviations (Luebke et al., 2004). Because the cost of mistakes in immune competence can be so high, and because of the tremendous diversity involved in the identification of self versus nonself, a complex array of organs, cells, soluble factors, and their interactions has evolved to regulate this system and minimize the frequency of errors in either direction. Due to the potentially profound effects resulting from disruption of the delicately balanced immune system, there is a need to understand the cellular, biochemical, and molecular mechanisms of xenobiotic-induced immune modulation.

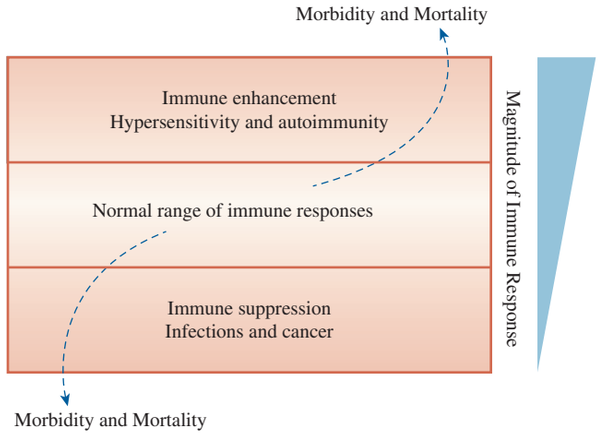

Figure 12-1. *The continuum of immunotoxicology.* Immune toxicity results from xenobiotic-induced suppression or enhancement of immune function.

This chapter provides (1) an overview of basic concepts in immunology (structure, components, and functions), which are important to the understanding of the impact xenobiotics may have on the exposed individual; (2) a summary of selected current methods utilized to assess immune function; and (3) a brief review of current information on the immune modulation (immune suppression, immune enhancement, hypersensitivity, and autoimmunity) induced by a variety of xenobiotics. This chapter is not meant to be an immunology textbook, nor an exhaustive review of the mechanisms of immunotoxicity of a myriad of xenobiotics. For detailed information on immunology, the reader is referred to three texts: the first edited by Paul, *Fundamental Immunology* (7th edition, 2013), the second written by Delves, Martin, Burton, and Roitt, *Roitt's Essential Immunology* (13th edition, 2017), and the third written by Murphy and Weaver, *Janeway's Immunobiology* (9th edition, 2016). For a more comprehensive review of immunotoxicology, the reader is referred to three texts: the first edited by Vohr and colleagues, *Encyclopedic Reference of Immunotoxicology* (2nd edition, 2016), the second edited by House and Luebke, *Immunotoxicology and Immunopharmacology, Target Organ Toxicity Series* (3rd edition, 2007), and the third edited by Corsini and Van Loveren, *Molecular Immunotoxicology* (1st edition, 2014). The reader might also find the list of abbreviations in Table 12-1 helpful.

THE IMMUNE SYSTEM

Unlike most organ systems, the immune system has the unique quality of not being confined to a single site within the body. It comprises numerous lymphoid organs (Table 12-2) and many different cellular populations and soluble factors with a variety of functions focused on providing immunity against nonself or exogenous substances (i.e., antigens). Immunity can be classified into two functional divisions: innate immunity and acquired (adaptive) immunity (Table 12-3). Innate immunity has historically been characterized as a first-line defense response with little immunological memory. Therefore, in healthy adults, the magnitude of the innate immune response to a foreign organism is similar for a secondary

Table 12-1

Abbreviations

TERM	ABBREVIATION	TERM	ABBREVIATION
Antibody-dependent cell-mediated cytotoxicity	ADCC	Lipopolysaccharide	LPS
Antibody forming cell	AFC	Local lymph node assay	LLNA
Antigen presenting cell	APC	Major histocompatibility complex	MHC
Antibody secreting cell	ASC	Membrane attack complex	MAC
Aryl hydrocarbon receptor	AhR	Mixed lymphocyte response	MLR
B-cell receptor	BCR	Neutrophil extracellular trap	NET
B-regulatory cell	Breg	National Toxicology Program	NTP
Carboxyfluorescein succinimidyl ester	CFSE	Natural killer cell	NK
CD40 ligand	CD40L	Natural T regulatory cell	nTreg
Cell-mediated immunity	CMI	NOD-like receptors	NLR
Central nervous system	CNS	Non-human primates	NHP
Cluster of differentiation	CD	Nuclear factor of activated T cells	NFAT
Colony stimulating factor	CSF	Nuclear factor κB	NF-κB
Common lymphoid progenitor	CLP	Pathogen-associated molecular patterns	PAMPs
Common myeloid progenitor	CMP	Pattern recognition receptors	PRR
Concanavalin-A	Con-A	Peripheral blood mononuclear cell	PBMC
Conventional dendritic cell	cDC	Phytohemagglutinin	PHA
Cyclooxygenase	COX	Plaque forming cell	PFC
Cytotoxic T lymphocyte	CTL	Plasmacytoid dendritic cell	pDC
Danger-associated molecular patterns	DAMPs	Polymerase chain reaction	PCR
Delayed-type hypersensitivity	DTH	Pre/postnatal development	PPND
Dendritic cell	DC	Reactive oxygen species	ROS
Developmental and reproductive toxicology	DART	RIG-like receptors	RLR
Developmental immunotoxicology	DIT	Reverse transcriptase	RT
Embryo fetal development	EFD	Sheep red blood cells	sRBCs
Experimental autoimmune encephalomyelitis	EAE	Single nucleotide polymorphism	SNP
Fc receptor	FcR	Systemic lupus erythematosus	SLE
Hematopoietic stem cell	HSC	T-cell-dependent antibody response	TDAR
Human lymphocyte activation	HuLa	T-cell-independent antibody response	TIAR
Human peripheral blood	HPB	T-cell receptor	TCR
Immunoglobulin	Ig	T-helper cell	Th
Interferon	IFN	Toll-like receptor	TLR
Inducible T regulatory cell	iTreg	T-regulatory cell	Treg
Innate lymphoid cell	ILC	Transforming growth factor	TGF
Interleukin	IL	Tumor necrosis factor	TNF
Keyhole limpet hemocyanin	KLH		

Table 12-2

Organization of the Immune System: Lymphoid Tissue

CLASSIFICATION	LYMPHOID ORGANS
Primary	Bone marrow Thymus
Secondary	Spleen Lymph nodes Peyer's patches Skin-associated lymphoid tissue (SALT) Mucosal-associated lymphoid tissue (MALT) Gut-associated lymphoid tissue (GALT) Bronchial-associated lymphoid tissue (BALT) Nasal-associated lymphoid tissue (NALT)
Tertiary	Cells lining the genitourinary tract Lymphoid neogenesis in nonlymphoid organs

or a tertiary challenge as it is for the primary exposure. By contrast, acquired (adaptive) immunity is characterized by antigen specificity and immunological memory. Thus, in healthy adults, the speed and magnitude of the acquired immune response to a foreign organism is greater for a secondary challenge than it is for the primary challenge.

All immune cells originate from the bone marrow, which is considered a primary lymphoid organ. The bone marrow contains a microenvironment capable of supporting immune cell production. As such the bone marrow is the site of origin of the pluripotent and self-renewing hematopoietic stem cell (HSC) from which all other hematopoietic cells are derived. While immunologists differ on how to define and identify the hematopoietic intermediates, Fig. 12-2 shows one model of hematopoiesis (adapted from Baltimore et al. [2008] and Chaplin [2010]). During gestation, the HSC is found in the embryonic yolk sac and fetal liver; eventually, it migrates to the bone marrow. Within the bone marrow, the HSC developmentally commits to either the lymphoid or myeloid lineages by giving rise to the common lymphoid progenitor (CLP) or the common myeloid progenitor (CMP), which differentiate into various types of hematopoietic cells that mediate innate and adaptive immunity.

Table 12-3

Innate versus Adaptive Immunity

CHARACTERISTIC	INNATE IMMUNITY	ACQUIRED IMMUNITY
Cells involved	Neutrophils Macrophages NK/NKT cells DC TCRγδ	T cells B cells Macrophages DC
Primary soluble mediators	Complement Perforin/Granzyme Acute-phase proteins IFN-α/β Other cytokines	Antibody Cytokines Perforin/Granzyme
Specificity of response	Limited	Very high specificity
Receptors	TLR complement receptors NLR FcR TCRγδ	TCRαβ TCRγδ BCR
Response enhanced by repeated antigen challenge	No	Yes

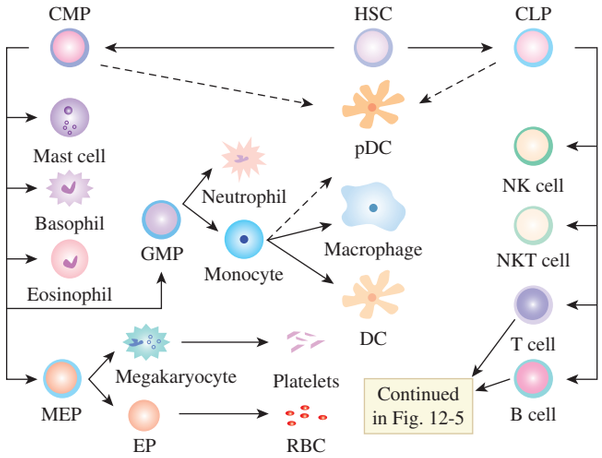

Figure 12-2. *Development of the cellular components of the immune system.* All immune cells initially develop in the bone marrow. The HSC differentiates into two main progenitors from which all other cells develop. The progenitor for pDCs is still unclear (dashed lines). CLP, common lymphoid progenitor; CMP, common myeloid progenitor; DC, dendritic cell; EP, erythrocyte precursor; GMP, granulocyte-macrophage progenitor; HSC, hematopoietic stem cell; MEP, megakaryocyte-erythrocyte progenitor; pDC, plasmacytoid dendritic cell; RBC, red blood cells.

Because effective immunity is the result of a coordinated multifunctional system, the various cells that comprise innate and acquired immunity must interact and communicate. Cells interact with antigens and each other via receptors, and often produce soluble factors termed cytokines and chemokines as means of cell–cell communication. The resulting actions by cells receiving messages in the form of cytokines and chemokines are diverse and include cellular activation, initiation or termination of intracellular signaling events, proliferation, differentiation, migration, trafficking, or effector functions. It is important to note that while some of these molecules might be constitutively expressed, most are inducible in response to antigens, cellular stressors, or other cytokines. Thus, many cytokines and chemokines are not stored in the cell, but are tightly regulated, often at the transcriptional level, so that they are quickly generated on demand. Moreover, many cytokines share common receptor subunits, which allows greater flexibility for a cell's responsiveness to these extracellular signals. A partial list of cytokines and a brief description of the cell types that release and are acted upon by these various mediators is provided in Table 12-4.

Innate Immunity

As stated above, innate immunity acts as a first line of defense against anything nonself. With respect to infectious agents, the innate immune system eliminates most potential pathogens before significant infection occurs. The innate immune system includes physical and biochemical barriers both inside and outside the body, as well as immune cells designed for host defense responses and soluble factors.

Externally, the skin provides an effective barrier, as most organisms cannot penetrate intact skin. Most infectious agents enter the body through the respiratory system, gut, or genitourinary tract. Innate defenses present to combat infection from pathogens entering through the respiratory system include mucus secreted along the nasopharynx, the presence of lysozyme in most secretions, and cilia lining the trachea and main bronchi. In addition, reflexes such as coughing, sneezing, and elevation in body temperature are also a part of innate immunity. Pathogens that enter the body via the digestive tract are met with severe changes in pH (acidic) within the stomach and a host of commensal bacteria (i.e., microbiota) living in the intestines that play a protective role.

Cellular Components: Neutrophils, Macrophages, Dendritic Cells, Natural Killer Cells, NKT Cells, γδ T Cells, and B-1 B Cells Several cell types are involved in innate immunity, and in fact, some also provide critical signals to initiate adaptive immune responses (Tables 12-3 and 12-5). Neutrophils (also known as polymorphonuclear leukocytes or PMNs) are phagocytic cells that develop from the myeloid lineage of HSCs. Neutrophils enter the bloodstream where they circulate for about 10 hours and then enter the tissues where they perform effector functions for about 1 to 2 days. Neutrophils are capable of passing between the endothelial cells of the blood vessels (i.e., extravasation) and thereby represent a primary line of defense against pathogens. They are excellent phagocytic cells and can eliminate most microorganisms through the release of various reactive oxygen species (ROS), such as superoxide, singlet oxygen, ozone, hydrogen peroxide, and hydroxyl radicals. Their phagocytic activity (i.e., ability to internalize foreign materials) is greatly enhanced by the presence of complement and antibody deposited on the surface of the foreign target (see the section "Antigen Recognition"). Neutrophils are also important in the induction of an inflammatory response (see the section "Inflammation").

Table 12-4

Cytokines: Sources and Functions in Immune Regulation

CYTOKINE	SOURCE	PHYSIOLOGIC ACTIONS
IL-1	Macrophages Epithelial cells	Activation and proliferation of T cells Pro-inflammatory Induces fever and acute-phase proteins Induces synthesis of pro-inflammatory cytokines
IL-2	T cells	Primary T-cell growth factor Growth factor for B cells and NK cells
IL-4	Th2 cells Mast cells	Proliferation of activated Th2 and B cells B-cell differentiation and IgE isotype switching Antagonizes IFN-γ Inhibits Th1 responses
IL-5	Th2 cells Mast cells	Proliferation and differentiation of eosinophils
IL-6	Macrophages Th2 cells B cells Endothelial cells	Enhances B-cell differentiation and Ig secretion Induction of acute-phase proteins by liver Pro-inflammatory Proliferation of T cells and increased IL-2 receptor expression
IL-10	Tregs Bregs Macrophages	Inhibits T-cell and macrophage responses
IL-12	DCs Macrophages	Activates NK cells Induces Th1 responses
IL-13	Th2 cells	Stimulates B-cell growth Inhibits Th1 responses
IL-17	Th17 cells NK cells γδ T cells Neutrophils	Pro-inflammatory Inhibits Tregs
IL-22	Th17 cells ILCs	Activates neutrophils Mucosal protection
IFN-α/β (Type I IFN)	Leukocytes DCs Fibroblasts	Induction of MHCI expression Antiviral activity Stimulation of NK cells
IFN-γ	T cells NK cells	Induction of MHCI and MHCII Activates macrophages
TGF-β	Macrophages Megakaryocytes T cells	Enhances monocyte/macrophage chemotaxis Enhances wound healing: angiogenesis, fibroblast Proliferation, deposition of extracellular matrix Inhibits T and B-cell proliferation Inhibits antibody secretion Primary inducer of isotype switch to IgA
GM-CSF	T cells Macrophages Endothelial cells Fibroblasts	Stimulates growth and differentiation of monocytes and granulocytes

SOURCE: Information on selected cytokines taken from Murphy and Weaver (2016).

Also important in the innate response are macrophages. Macrophages are terminally differentiated monocytes, which develop from the myeloid lineage of HSCs (Fig. 12-2). Upon exiting the bone marrow, monocytes circulate within the bloodstream for about 1 day. At that time, they begin to distribute to the various tissues where they can then differentiate into distinct macrophage populations. Tissue-specific macrophages include Kupffer cells (liver), alveolar macrophages (lung), microglial cells (CNS), and peritoneal and splenic macrophages. These tissue-specific macrophages have distinct properties and vary in the extent of surface receptors, oxidative metabolism, and expression of major histocompatibility complex class II (MHCII), due to the factors

present within the microenvironment in which the cells reside. Macrophages can be classified as classically activated macrophages (M1), which are pro-inflammatory, or alternatively activated macrophages (M2), which are efficient at apoptotic cell removal and tissue remodeling and repair (reviewed by Martinez and Gordon [2014]). Macrophages also act as antigen-presenting cells (APCs; see the section "Antigen Recognition").

Another critical innate cell is the dendritic cell (DC; also see the section "Antigen Processing"). DCs are critical to innate immunity because they survey their environment for pathogens, then mature to become highly efficient APCs. Thus, they provide a bridge between initial detection of an infectious agent and elicitation of adaptive immune responses. DCs can be classified into several subsets and it is thought that the various subsets develop from either CLPs or CMPs, although the exact details are still unclear (reviewed by Watowich and Liu [2010]). Although not reviewed here, a challenge with lineage definition is the extensive heterogeneity of cell surface proteins expressed by DC populations, including varying expression of CD11b, CD11c, MHCII, CD4, CD8, and CD205 (reviewed by Watowich and Liu [2010]). All DCs possess efficient APC activity and cytokine production (Watowich and Liu, 2010), but may also possess specialized functions. Plasmacytoid dendritic cells (pDCs), for instance, secrete large amounts of Type I interferons (IFNs), such as IFN-α, which is necessary for T-cell differentiation and antiviral activity (Sachdeva et al., 2008).

Like other immune cells, NK cells are derived from a CLP (Fig. 12-2). NK cells belong to a larger family of cells defined as innate lymphoid cells (ILCs), which play roles in innate immunity and inflammation, particularly during the initial phases of inflammation prior to T-cell differentiation (Spits and Di Santo, 2011; Vanaudenaerde et al., 2011). NK cells have two major functions, cytokine production and destroying virus-infected or neoplastic target cells. NK cells are a predominant source of IFN-γ, which helps mature DCs and activate macrophages (Vivier et al., 2011). Thus, NK cells also help to bridge innate-adaptive immunity. NK cells mediate both antibody-independent and antibody-dependent cellular cytotoxicity (ADCC) using a variety of mechanisms, including perforin and granzyme, Fas ligand, tumor necrosis factor–related apoptosis-inducing ligand (TRAIL), and TNF-α. ADCC occurs via an FcR (FcγRIIIA), which is present on most NK cell subsets. Invariant NKT (iNKT) cells are one such subset of NK cells that express both NK- and T-cell markers and are restricted to recognition of microbial glycolipids presented by CD1d, a MHCI-like molecule (Diana and Lehuen, 2009).

Another cell type that has been found to bridge innate-adaptive immunity is the $\gamma\delta$ T cell. These cells migrate predominantly to "exposed" tissues, including skin, lung, gut, and reproductive organs, and are also expressed highly in the liver (Bonneville et al., 2010). In part through the expression of Toll-like receptors (TLRs), which are discussed in more detail below, $\gamma\delta$ T cells can acquire effector functions similar to NK cells (cytokine production and cytotoxicity). There is also a subpopulation of B cells (i.e., $CD5^+$ or B-1 cells) that bridge between innate immunity and adaptive immunity. Unlike the conventional B-2 cells, B-1 cells predominate in embryonic life and are later found mostly in the peritoneal and pleural cavities. B-1 cells are self-renewing and spontaneously produce polyspecific IgM antibodies (i.e., antibodies directed primarily against capsular polysaccharide antigens) independent of T-cell help (Baumgarth, 2011).

Historically, innate immunity was defined as nonspecific. It is now clear that innate cells express receptors that respond to soluble components (e.g., Fc or complement receptors) or to certain antigenic motifs. Pattern recognition receptors are a family of receptors that recognize pathogen-derived molecules (pathogen-associated molecular patterns [PAMPs]) or cell-derived molecules produced in response to cellular stress (danger-associated molecular patterns [DAMPs]). Receptors that recognize PAMPs or DAMPs include TLRs, NOD-like receptors (NLRs), and RIG-like receptors (RLRs) (Davis et al., 2011). Several TLRs are expressed extracellularly, and several are expressed intracellularly in endosomes, in order to protect against extracellular and intracellular pathogens, respectively. Moreover, this diverse localization of TLRs allows cells to respond to a variety of pathogenic components, such as bacterial cell wall lipids, single- and double-stranded nucleic acids, or fungal and parasitic products (Chang, 2010). Functional consequences of TLRs include expression of adhesion molecules, chemokines, or cytokines to stimulate T- or B-cell differentiation, enhance phagocytosis, or induce maturation of DCs (Chang, 2010). NLRs and RLRs are expressed in many innate cells. Several family members of NLRs participate in a complex called the inflammasome, which activates inflammatory caspases to enhance production of mature interleukin (IL)-1β and IL-18 (Martinon et al., 2009).

Soluble Components: Acute-Phase Proteins, Granzyme, Perforin, and Complement Acute-phase proteins, such as serum amyloid A, serum amyloid P, and C-reactive protein, participate in an acute-phase response to infection by binding bacteria and facilitating complement activation. Granzyme and perforin work in conjunction, with perforin disrupting the target cell membrane, allowing granzyme to enter and mediate cell lysis by several mechanisms.

The complement system is a family of about 30 serum proteins, which functions to destroy the membranes of infectious agents, facilitate phagocytosis of foreign materials, and promote an inflammatory response (reviewed by Stoermer and Morrison [2011]; also see the section "Inflammation"). Complement activation occurs with each component sequentially acting on other components in a manner similar to the blood-clotting cascade (Fig. 12-3). Proximal components of the cascade are often modified serine proteases, which activate the system but have limited substrate specificity. Several components are capable of binding to microbial membranes and serve as ligands for complement receptors on phagocytic cells to facilitate phagocytosis, although a primary pathway of complement activation occurs after antibody binds a pathogen. The final components, which are related structurally, are also membrane-binding proteins that form the membrane attack complex (MAC), which enters into the membrane and disrupts membrane integrity.

Specifically, three pathways have been identified in activation of the complement cascade. The classical complement pathway is initiated when antibody binds antigen on the microorganism. The classical pathway then proceeds by activating a C1 subunit serine protease, subsequently recruiting C4, C2, and C3. Various cleavages ultimately result in C3b surface binding to the surface of the microorganism and release of C3a, a pro-inflammatory mediator (see the section "Inflammation"). Microorganism-bound C3b can then be recognized by complement receptors on phagocytic cells, which engulf and destroy the microorganism. It is also at this point that the alternative pathway can be activated and amplifies the complement-mediated killing of the microorganism. Finally, C3b mediates recruitment of C5, which is cleaved, generating C5b on the surface and releasing C5a, another pro-inflammatory mediator (see the section "Inflammation"). Microorganism-bound C5b recruits C6 and

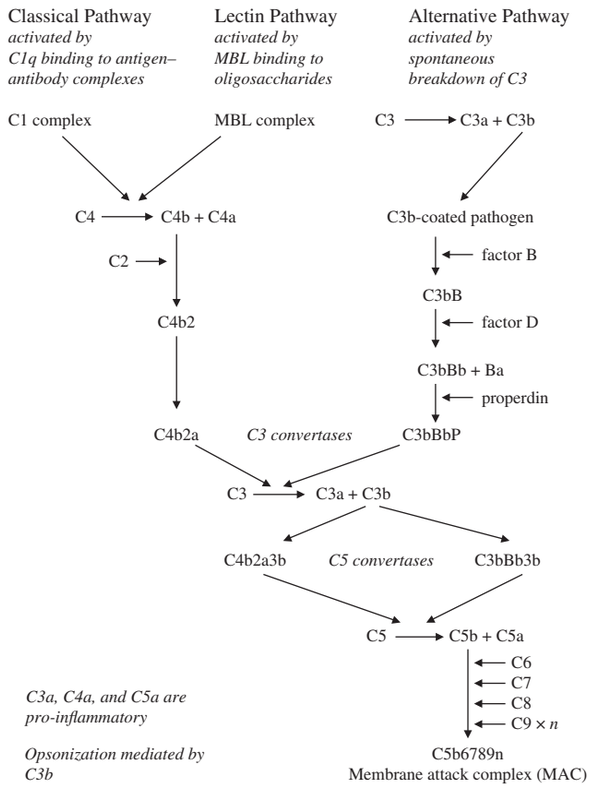

Figure 12-3. *The complement cascade.* The complement cascade can be activated in three different ways. Cytolysis occurs via generation of the MAC. Various complement proteins generated along the pathway are either pro-inflammatory (C3a, C5a) or result in opsonization (C3b).

C7, which together form a complex and recruit C8. C9 is ultimately recruited, polymerizes, and forms a pore in the membrane of the microorganism, causing its death. In addition to the classical and alternative pathways, complement-mediated lysis is also activated through the lectin pathway, in which binding of mannose-binding lectin (MBL) to the surface of the microorganism activates the pathway and converges with the classical pathway at C4 (Fig. 12-3).

A functional outcome of complement activation, in addition to cytolysis and generation of pro-inflammatory mediators, is opsonization, the process by which microorganisms are coated by opsonins (predominantly IgM and IgG antibodies and C3b), rendering them vulnerable to phagocytosis by cells (usually macrophages and neutrophils) (Dunkelberger and Song, 2010). Therefore, in combination with C3b opsonization and IgG antibodies recognizing extracellular antigens, phagocytic cells efficiently engulf the microbe through complement receptors or Fc receptors specific for IgG.

Antigen Recognition

A critical step in the initiation of acquired immunity is the ability of immune cells to recognize nonself. Nonself molecules need to be processed and presented by APCs to initiate the cell-mediated and humoral response by T and B cells, respectively.

Antigen As stated earlier, a nonself substance that can be recognized by the immune system is called an antigen (also referred to as an immunogen or allergen). Antigens are usually (but not absolutely) biological molecules that can be cleaved and rearranged for presentation to other immune cells. Generally, antigens are about

Table 12-6

Properties of Immunoglobulin Classes and Subclasses

CLASS	MEAN SERUM CONCENTRATION (MG/ML)	HUMAN HALF-LIFE DAYS	BIOLOGICAL PROPERTIES
IgG			Complement fixation (selected subclasses) Crosses placenta
IgG_1	9	21	
IgG_2	3	20	
IgG_3	1	7	
IgG_4	1	21	
IgA	3	6	Secretory antibody
IgM	1.5	10	Complement fixation Efficient agglutination
IgD	0.03	3	Possible role in antigen-triggered lymphocyte differentiation
IgE	0.0001	2	Allergic responses (mast cell degranulation)

10 kDa or larger in size. Smaller antigens are termed "haptens" and must be conjugated with carrier molecules (larger antigens) in order to elicit a specific response. However, once an initial response is made, the hapten can induce subsequent responses in the absence of the carrier.

Antibodies Antibodies are produced by B cells and are defined functionally by the antigen with which they react, and by their subtype, termed "isotype" (IgM, IgD, IgG, IgE, and IgA; Table 12-6). Thus, an IgM antibody directed against sheep red blood cells (sRBCs) is called anti-sRBC IgM. Because the immune system generates antibodies to thousands of antigens with which the host may or may not ever come into contact, antibodies of unknown specificity are referred to as immunoglobulin (e.g., serum immunoglobulin or serum IgM) until defined by their specific antigen (e.g., anti-sRBC IgM).

The ability of the immune system to generate antibody to thousands of antigens is the result of somatic recombination, in which the germline DNA that encodes for antibodies is rearranged in B cells. All Igs are made up of heavy and light chains and of constant and variable regions. For the light chain genes, two separate gene segments (V and J) are combined to form the variable region, which is then joined to one constant region. For the heavy chain genes, three separate gene segments (V, D, and J) are combined to form the variable region, which is then joined to the constant region. There are several light chain V and J gene segments, and several heavy chain V, D, and J gene segments, which can rearrange in various combinations to contribute to the immense genetic diversity of the Ig genes (Fig. 12-4). Finally, the five types of Ig are dependent on which heavy chain constant region is transcribed and translated (heavy chain genes μ, γ, ε, δ, or α encode for the IgM, IgG, IgE,

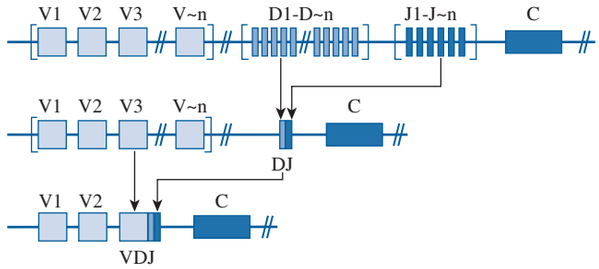

Figure 12-4. *Ig recombination.* An example of VDJ recombination that might occur for Ig heavy chain in B cells or TCR β chain in T cells. Ig light chain in B cells or TCR-α chain in T cells is similar, but does not include D gene segments.

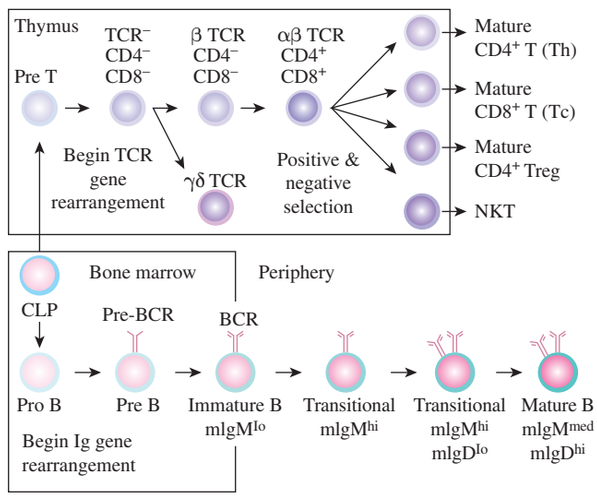

Figure 12-5. *Development and differentiation of T and B cells.* T cells develop in the thymus and B cells develop in the bone marrow. For T cells, an initial step is commitment to either αβ or γδ TCR. After positive and negative selection, T cells acquire either CD4 or CD8 to become Th or CTL, respectively. T cells can also become natural Tregs (nTregs) or NKT cells. The B-cell lineage depicted here is of the conventional B-2 lineage. B-1 cells are not depicted since these cells arise from a distinct precursor not found in the bone marrow, which might be a precursor that can generate B-1 or myeloid cells. mIg refers to membrane-bound immunoglobulin.

IgD, or IgA heavy chain proteins, respectively). Immunoglobulin gene rearrangement occurs in the bone marrow during B-cell development (Fig. 12-5). B-cell maturation also involves the establishment of central tolerance (i.e., nonreactive to self-antigens) to prevent the maturation of lymphocytes that recognize self-antigens. For B cells, central tolerance occurs in the bone marrow and simply involves the removal of self-reactive cells.

The variable regions, which are contained within the Fab regions of the antibody molecule, determine antibody specificity and interact with antigen (Fig. 12-6). The Fc region mediates various effector functions, such as complement activation (IgM and some IgG subclasses) and phagocyte binding (via Fc receptors). Antibodies possess several functions: (1) opsonization, which is coating of a pathogen with antibody to enhance Fc receptor–mediated endocytosis by phagocytic cells; (2) initiation of the classic pathway of complement-mediated lysis; (3) neutralization of viral infection by binding to viral particles and preventing further infection; and (4) enhancement of the specificity of effectors of cell-mediated immunity (CMI) by binding to specific antigens on target

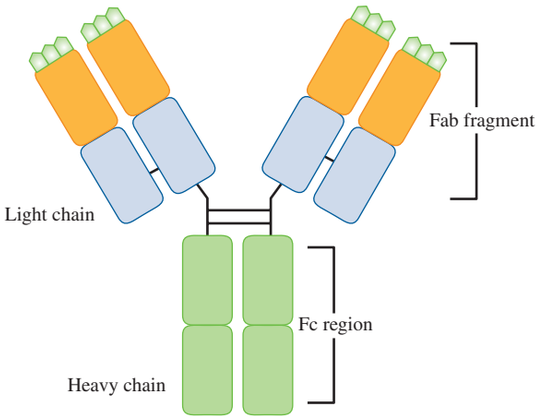

Figure 12-6. *Ig structure.* Igs are comprised of two heavy chains and two light chains, which are connected by disulfide bonds. Gold areas are variable regions and green areas are antigen recognition regions.

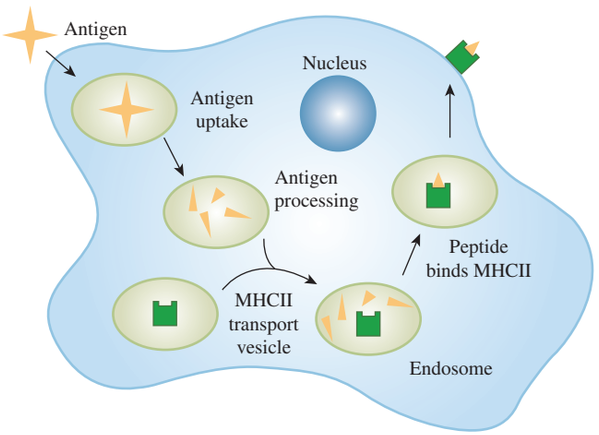

Figure 12-7. *Antigen processing by the MHCII pathway.* Antigen is engulfed by an APC (DC, macrophage, or B cell), degraded and loaded onto MHCII. The MHCII–peptide complex is then expressed on the surface of the APC for presentation to $CD4^+$ Th cells.

cells, which are then recognized and eliminated by effector cells such as natural killer (NK) cells or cytotoxic T lymphocytes (CTLs).

Antigen Processing In order to elicit an acquired immune response to a particular antigen, that antigen must be taken up and processed by accessory cells for presentation to lymphocytes. As introduced earlier, accessory cells that perform this function are termed APCs and include macrophages, DCs, and B cells. Of these, the most proficient APC is the DC. There are several subtypes of DC, including plasmacytoid (pDCs), conventional (cDCs; can be resident or migratory depending on whether they migrate to the site of infection), and specialized DCs in the skin called Langerhans cells. In addition, there are follicular DCs, which predominantly mediate T-cell-independent stimulation of B cells in germinal centers (Vinuesa et al., 2010).

In most tissues in the absence of antigenic stimulation, DCs are in an immature state, during which they efficiently capture antigens. DCs can mature in response to antigen itself, TLR agonists such as lipopolysaccharide (LPS), or cytokines (e.g., granulocyte-macrophage colony-stimulating factor [GM-CSF], or TNF-α) (Banchereau and Steinman, 1998). Upon maturation, DCs migrate to lymph nodes and present antigen to T cells. Thus, the DC–T-cell interaction is critical for the development of an acquired immune response.

Immature DCs internalize the antigen either by phagocytosis, pinocytosis, or by receptor-mediated endocytosis (via antigen, Fc, or complement receptors), after which the DCs mature to express high levels of both classes of MHC (MHCI and MHCII) to stimulate innate and adaptive immune responses, and costimulatory molecules to facilitate interaction with T cells (Banchereau and Steinman, 1998). Interestingly, Langerhans cells express high levels of MHCII even in a resting state (i.e., nonactivated) (Kaplan, 2010). Following internalization, antigen is processed (intracellular denaturation and catabolism) through several cytoplasmic compartments, and a piece of the antigen (peptide fragments about 20 amino acids in length) becomes physically associated with MHCII (Fig. 12-7). This MHCII–peptide complex is then transported to the surface of the cell and can interact in a specific manner with T lymphocytes. For most APCs, an immunogenic determinant is expressed on the surface of the APC within an hour after internalization, although this is slightly longer for B cells (3 to 4 hours). In addition to processing and presentation, pieces of processed antigen may be expelled into the extracellular space. These pieces of processed antigen can then bind in the peptide groove of empty MHCII on the surface of other APCs for the presentation of that peptide fragment to lymphocytes.

In addition to antigen processing and presentation via MHCII, some antigens may be processed and presented via MHCI. Although the pathways share some similarities in that short peptide fragments of antigens are generated, loaded onto MHC, and presented on the surface of cells to T lymphocytes, major differences between the MHCI and MHCII pathways are (1) antigens processed and presented via MHCI are not limited to professional APC; (2) all nucleated cells express MHCI; (3) the mechanisms by which the antigen is processed and loaded onto MHCI are slightly different than MHCII; (4) the MHCI antigenic peptides are usually smaller, often 8 to 10 amino acids in length; (5) the MHCI antigens to be processed are usually aberrantly expressed proteins, such as viral-associated proteins or mutated proteins; and (6) MHCI facilitates antigen presentation to $CD8^+$ T cells, whereas MHCII facilitates antigen presentation to $CD4^+$ T cells. MHCI antigen processing and presentation is the major pathway by which virally infected cells are detected and killed by the acquired immune system.

Regardless of the MHC utilized to present antigens to lymphocytes, T cells are able to recognize antigen in the context of MHC with their T-cell receptor (TCR). Similar to Ig, the ability of T cells to specifically recognize thousands of antigens is due to somatic recombination. All TCRs are comprised of two different subunits, each encoded from a distinct gene (most abundant T-cell population expresses the αβ subunits, but γδ also exist). All TCR subunits are made up of constant and variable regions. For α subunits, two separate gene segments (V and J) are combined to form the variable region, which is then joined to a constant region. For β subunits, three separate gene segments (V, D, and J) are combined to form the variable region, which is then joined to a constant region. Similar to the Ig genes, there are several α subunit V and J gene segments, and several β subunit V, D, and J gene segments (Fig. 12-4). TCR gene rearrangement occurs during T-cell and iNKT cell development in the thymus. iNKT cells express an invariant TCR that recognizes microbial glycolipids in the context of the MHCI-like molecule CD1d.

Although CLP cells originate in the bone marrow and give rise to B cells, NK cells, T cells, and iNKT cells, the latter two cell types do not develop in the bone marrow. Instead T-cell progenitors migrate from the bone marrow to the thymus, (i.e., a primary

lymphoid tissue specific for T-cell development; Figs. 12-2 and 12-5). The maturation process for T cells involves the establishment of central tolerance, which is a state of non-responsiveness to self. It is complex for T cells and involves both positive and negative selection resulting in mature T cells that recognize self-peptide loaded MHC (or CD1d for iNKT cells) on the host's cells (i.e., positive selection) but not too strongly. T cells that recognize self too strongly are deleted from the T-cell repertoire (termed negative selection).

With regard to T and B cells, key events that occur following antigen encounter are (1) specific antigen recognition either in the context of MHCI or MHCII for T cells or through the Ig receptor for B cells; (2) cellular activation and initiation of intracellular signaling cascades that contribute to production and release of cytokines and other cellular mediators; (3) clonal expansion (proliferation) of antigen-specific cells; and (4) differentiation of antigen-stimulated lymphocytes into effector and memory cells. These processes are detailed below.

Acquired (Adaptive) Immunity

If the primary defenses against infection (innate immunity) are breached, the acquired arm of the immune system is activated and produces a specific immune response to each infectious agent, which usually eliminates the infection. This branch of immunity is also capable of remembering the pathogen and can protect the host from future infection by the same agent. Therefore, the two key features that define acquired immunity are specificity and memory. Acquired immunity may be further subdivided into humoral and cell-mediated immunity (CMI). Humoral immunity is directly dependent on the production of antigen-specific antibody by B cells and involves the coordinated interaction of APCs, T cells, and B cells. CMI is that part of the acquired immune system in which effector cells, such as phagocytic cells, T helper cells, regulatory T cells, APCs, cytotoxic T cells, or memory T cells, play the critical role(s) without antibody involvement.

Mature, naive, or virgin lymphocytes (those T and B cells that have never undergone antigenic stimulation) are first brought into contact with exogenously derived antigens within the highly organized microenvironment of the spleen and lymph nodes, which are secondary lymphoid organs. These organs can be thought of as biological sieves. The spleen serves as a filter for the blood, removing both foreign antigens and any circulating dead cells and cellular debris. The lymph nodes are part of a network of lymphatic veins that filter antigens from the fluid surrounding the tissues of the body. In addition to the spleen and lymph nodes, other secondary lymphoid tissues associated with the skin, gut, bronchioles, or nasal cavity are referred to as associated lymphoid tissues (abbreviated SALT, GALT, BALT, and NALT, respectively; Table 12-2). MALT is a general term for all mucosal-associated lymphoid tissues. Included in the GALT are isolated lymphoid follicles and specialized structures in the small intestine called Peyer's patches, both of which collect antigens from the gastrointestinal tract. The associated lymphoid tissues tend to have more exposure to antigen and greater plasticity (i.e., increase or decrease in size and/or number) than lymph nodes. The plasticity of lymphoid organs is underscored by the detection of lymphoid neogenesis in nonlymphoid organs during chronic inflammation. The new lymphoid tissue is classified as tertiary lymphoid tissue, and its development is reversible if the inflammatory response is resolved. A role for innate lymphocytes (ILCs) in development of tertiary lymphoid tissue has recently been identified (Pearson et al., 2012).

Cellular Components: Antigen-Presenting Cells, T Cells, and B Cells APCs, which were discussed previously in the section "Antigen Processing," include professional APCs such as B cells, macrophages, and DCs. Although all cells may act as APCs with internal antigen processing through the MHCI pathway, what distinguishes a professional APC from the others is the ability to internalize external antigens and process them through the MHCII pathway for presentation to T helper cells.

B cells are not only capable of serving as professional APCs, but they are also the effector cells of humoral immunity, producing a number of Ig isotypes with varying specificities and affinities. Like other immune cells, the B cell develops in the bone marrow from the HSC and becomes committed to the B-cell lineage when the cell begins to rearrange its Ig genes, as described in the section "Antigen Recognition" (Figs. 12-4 and 12-5). Following successful rearrangement of the heavy chain, these cells express Ig heavy chains in their cytoplasm and are termed pre-B cells. Successful rearrangement of the light chain results in expression of membrane-bound IgM in association with Igα and Igβ to form the B-cell receptor (BCR). Expression of membrane IgM and IgD BCRs indicates a mature B cell. B-1 B cells predominate in embryonic life and are later found mostly in the intestinal mucosa (Hardy, 2006). These cells are probably associated with innate immunity and are long-lived, self-renewing cells that produce high levels of polyspecific IgM (Baumgarth, 2011). Mature B cells of the conventional B-2 subset are found in the lymph nodes, spleen, and peripheral blood. Upon antigen binding to the BCR, the mature B cell becomes activated and, after proliferation, undergoes differentiation into either an antibody-forming cell (AFC) or a memory B cell. AFCs, also known as plaque-forming cells (PFCs), antibody-secreting cells (ASCs), or plasma cells, actively secrete antibody specific for the antigen that initially bound and activated the BCR. A broad description of several B-cell characteristics can be found in Table 12-5.

In a manner analogous to B cells, at a specified time following their commitment to the T-cell lineage, T-cell precursors migrate from the bone marrow to the thymus where they begin to rearrange their TCRs, as described in the section "Antigen Recognition" (Fig. 12-5). The TCR consists of two chains, either $\alpha\beta$ or $\gamma\delta$. The majority of T cells express the $\alpha\beta$ TCR, which is critical for the recognition of antigens in the context of MHC. A much smaller population of T cells express a $\gamma\delta$ TCR. The $\gamma\delta$ T cells differ from $\alpha\beta$ T cells in that they do not require antigen processing or presentation by MHC but instead directly bind intact host and pathogen proteins. Like the B-1 lineage, the $\gamma\delta$ T cells are expressed first in embryonic development and may be associated with innate immunity (see the section "Innate Immunity"). T cells committed to the $\alpha\beta$ lineage will express the surface markers CD4 and CD8. CD4 and CD8 are co-receptors expressed by $\alpha\beta$ T cells and are involved in the interaction of the T cell with MHC. T cells expressing $\alpha\beta$ TCR and both CD4 and CD8 are termed immature double-positive cells ($CD4^+$/$CD8^+$). These immature cells then undergo positive and negative selection to (1) select TCRs with affinity for self-MHC (positive selection) and eliminate cells that do not produce a functional TCR or produce TCRs with no affinity for self-MHC or (2) eliminate cells that strongly bind MHC plus self-peptide (negative selection). Double-positive cells that survive positive and negative selections will give rise to T cells that lose expression of either CD4 or CD8 and enter the periphery as mature single-positive cells ($CD4^+$ or $CD8^+$) with a high level of $\alpha\beta$ TCR expression. This rigorous selection process produces T cells that can recognize MHC plus foreign peptides and eliminates autoreactive T cells. Additionally, expression of CD4 or CD8 will determine to which MHC class the $\alpha\beta$ TCR will bind. CD4 will facilitate binding to MHCII expressed on APCs; T cells expressing CD4 (T helper cells [Th]) help activate other cells of the adaptive immune response. CD8 will facilitate binding to MHCI, which is expressed on all nucleated cells;

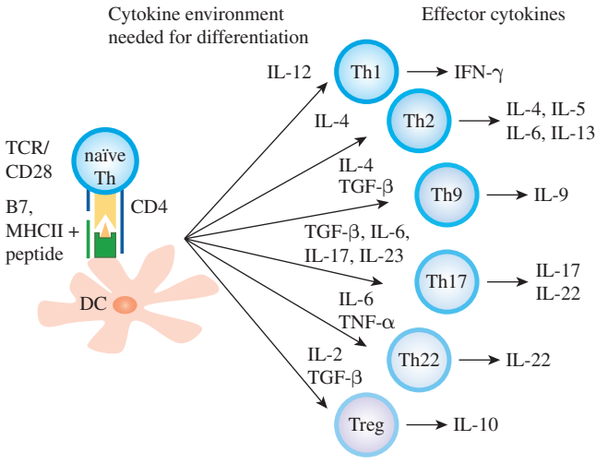

Figure 12-8. *The cytokine environment drives different Th populations.* Various Th cells (and T regulatory cells, Tregs) are differentially induced in response to the cytokine milieu. Th1 cells drive CTL responses; Th2 cells drive humoral immune responses; Th9, Th17, and Th22 all produce pro-inflammatory cytokines; Tregs control other T-cell responses.

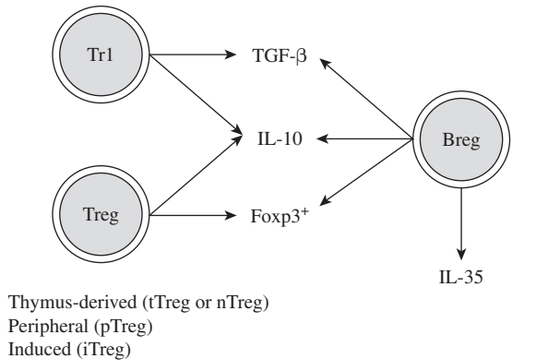

Figure 12-9. *Tregs and Bregs.* There are at least three different subpopulations of Tregs and Bregs, all of which suppress immune function via IL-10 or TGF-β. Tregs can be natural (thymus-derived) or induced in the periphery.

generally, T cells expressing CD8 mediate cell killing (cytotoxic T lymphocytes [CTL]). A broad description of several T-cell characteristics (specific to αβ T cells) can be found in Table 12-5. In contrast to αβ T cells, the γδ T cells do not express CD4 or CD8 and therefore do not interact with MHC and do not undergo positive or negative selection.

Mature T cells are found in the lymph nodes, spleen, and peripheral blood. Upon binding of the TCR to antigen in the context of MHC, the T cell becomes activated and, after proliferation, undergoes differentiation into either an effector cell or a memory T cell. Effector Th cells can subsequently differentiate into several phenotypes depending on the cytokine milieu (Fig. 12-8), two of which, Th1 or Th2, dictate whether CMI or humoral immunity will predominate, respectively. Th1 cells predominantly express IL-2, IFN-γ, and lymphotoxin, which promote CMI and humoral defense against intracellular invaders. Th2 cells predominantly express IL-3, IL-4, IL-5, IL-6, IL-10, and IL-13, which promote humoral defense against extracellular invaders. Although the two populations are not mutually exclusive, they do negatively regulate each other, such that a strong Th1 response suppresses a Th2 response and vice versa.

Th17, Th9, and Th22 cells have been shown to be critical for inflammatory responses (see the section "Inflammation"), and several studies including autoimmune models and clinical studies support a role of Th17 cells in inflammation and autoimmune diseases. Modulation of Th17 cellular function by xenobiotics may alter these disease states. Conversely, a better understanding of the relationship between Th17 and specific disease states has led to new therapeutics in the treatment of autoimmune and inflammatory diseases (Hemdan et al., 2010; Kimura and Kishimoto, 2011; Bartlett and Million, 2015).

The ability of APCs, B cells, and T cells to communicate with each other is dependent on a variety of receptor–ligand interactions between cell types. These interactions also help dictate the type of immune response (i.e., humoral vs. CMI) and the magnitude of the immune response. For example, TCR binding by antigen presented in the context of MHC is the major interaction that must occur between APCs and T cells to initiate an acquired immune response. Subsequent to this initial interaction, costimulatory molecules must be engaged on both the T cells and APCs to sustain and direct the immune response. One of the best characterized interactions occurs between CD28 on the T cells and CD80 or CD86 (B7.1 and B7.2) on the APCs, which provides a more robust immune response as measured by clonal expansion and cytokine (e.g., IL-2) production. Later in the response (2 to 3 days), T cells express CTLA-4, which exhibits higher affinity for CD80/CD86 than does CD28, and the CTLA-4–CD80/CD86 interaction serves as an immune checkpoint to suppress the T-cell response. Other important interactions between APCs and T cells include (1) CD40 and CD40 ligand (CD40L), which sustains clonal expansion and differentiation of the T cells and provides activation signals to the APC; (2) inducible T-cell costimulator (ICOS [CD278], a member of the CD28 superfamily) and ligand for ICOS, which sustains clonal expansion and differentiation of the T cells and induces IL-10 production; and (3) 4-1BB (CD137/Ly63, a member of the TNF receptor superfamily) and 4-1BB ligand, which sustains clonal expansion of the T cells and helps to activate the APC. CD40 ligand, ICOS, and 4-1BB are expressed on T cells. Therapeutic drugs that bind some of these costimulatory surface molecules have been developed and utilized clinically to either suppress immune function for transplantation and autoimmune therapy or stimulate immune function for cancer treatment, which will be discussed in the section "Therapeutic Drugs." For simplicity, in figures throughout the chapter, only the CD28–B7 interaction is depicted.

The duration and extent of an acquired immune response is also controlled by specialized regulatory cells found in both the T-cell and B-cell lineages, and there are considerable functional similarities between the different regulatory subsets found within both lineages (reviewed by Noh and Lee [2011]) (Figs. 12-8 and 12-9). For the T-cell lineage, there is a small population of $CD4^+$ cells that develop into T-regulatory cells (Tregs), which help to control various immune responses, including those directed against self. Tregs are generally identified as $CD4^+CD25^+Foxp3^+$, which are defined as natural Tregs (nTregs) if they develop in the thymus (Lio and Hsieh, 2011), but can also be induced (iTregs) in the periphery in response to IL-2 and TGF-β (Horwitz et al., 2008). Tregs can suppress $CD4^+$ and $CD8^+$ IL-2 production and proliferation, and in vivo have been shown to suppress autoimmune disease (Sakaguchi et al., 2009). Immune suppression by Tregs is likely a multistep process, which might involve direct cell killing via granzyme or perforin, induction of intracellular cAMP, or affecting cell surface expression of critical proteins, such as CD80/CD86. For instance, Foxp3 induces high levels of CTLA-4, which would interact with target cell CD80/CD86 and prevent target cell

CD80/CD86 from interacting with CD28 on other stimulatory cells (reviewed by Sakaguchi et al. [2009]). It has also been suggested that the high expression level of CD25 on Tregs might act as a reservoir for IL-2 in an immune synapse microenvironment, thereby preventing IL-2 from stimulating surrounding cells (Sakaguchi et al., 2009). In addition to Tregs, other regulatory T-cell subsets have been identified such as the IL-10-producing, FoxP3$^-$ Tr1 cells and the TGF-β-producing Th3 cells; all three regulatory subsets appear to be involved in regulating immune responses (Noh and Lee, 2011). Regardless of the processes that direct Treg (or perhaps Tr1 and Th3) suppression of immune function, their induction has been identified as one mechanism by which drugs and xenobiotics might result in immune suppression (Marshall and Kerkvliet, 2010; Ohkura et al., 2011). Like the regulatory T cells, several subsets of regulatory B cells (Bregs) are emerging and several reviews have been devoted to outlining the experimental evidence for specific regulatory B-cell subpopulations and their generally suppressive role in hypersensitivity and autoimmune diseases. Specifically, Bregs have been identified in controlling immune diseases such as allergic rhinitis (Xu et al., 2016b), collagen-induced arthritis (Park et al., 2016), chronic graft versus host disease (Sarvaria et al., 2016), and autoimmune disease (Huarte et al., 2016; Korniotis et al., 2016; Lehmann-Horn et al., 2016; Menon et al., 2016). The mechanism by which Bregs act involves induction of apoptosis-triggering molecules such as Fas ligand or production of immunosuppressive cytokines, IL-10 and IL-35. The regulatory T- and B-cell subsets also appear to reciprocally activate or suppress each other and may cooperatively control immune responses. The interplay between regulatory T- and B-cell subsets and their impact on immune responses, including autoimmune and allergic diseases, are important areas of investigation that will likely lead to a better understanding of immune pathologies including those induced by drugs and other xenobiotics.

Humoral and Cell-Mediated Immunity As described earlier, there are two branches of acquired immunity, humoral immunity and CMI. Humoral immunity is that part of the acquired immune system in which antibody is involved. In general, B cells produce antibodies specific to an antigen, which may act to opsonize or neutralize the invader, or the antibodies act to recruit other factors, such as the complement cascade. CMI is that part of the acquired immune system in which various effector cells perform a wide variety of functions to eliminate invaders. Often, these two branches are coordinated, such as activation of Th cells that produce specific cytokines that enhance B-cell proliferation and differentiation to secrete more antibody. A general diagram of the cellular interactions involved in a humoral immune response is given in Fig. 12-10. The production of antigen-specific IgM requires 3 to 5 days after the primary (initial) exposure to antigen (Fig. 12-11). Upon secondary antigenic challenge, the B cells undergo isotype switching, producing primarily IgG antibody, which is of higher affinity for the activating antigen due to a process called somatic hypermutation and affinity maturation. Somatic hypermutation involves introducing point mutations within the DNA of the variable region to induce conformational changes that may result in a higher affinity interaction between antigen and antibody. In addition, there is a higher serum antibody titer associated with a secondary antibody response. CMI functions include delayed-type hypersensitivity (DTH) and cell-mediated cytotoxicity. Cell-mediated cytotoxicity responses may occur in numerous ways: (1) MHC-dependent recognition of specific antigens (such as viral particles or tumor proteins) by CTLs or iNKT cells (CTL depicted in Fig. 12-12); (2) indirect antigen-specific recognition by the binding of Fc receptors

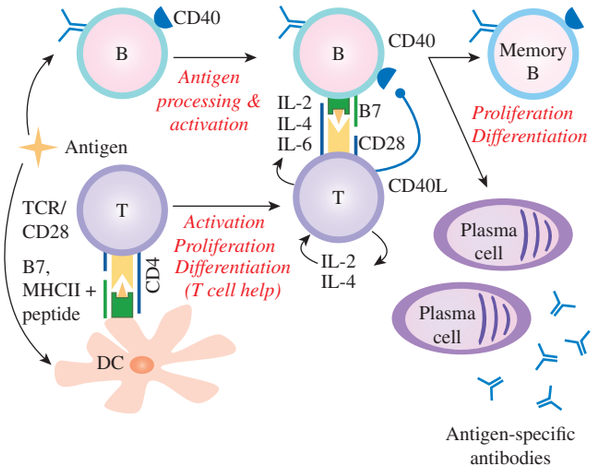

Figure 12-10. *Cellular interactions in the humoral immune response.* Antigen is engulfed by an APC (usually DC) and the antigenic peptide is presented to CD4$^+$ T cells in the context of MHC II. CD4$^+$ T cells then become activated, proliferate, and differentiate into Th cells, which release cytokines to help B cells that had also encountered the same antigen. B cells become activated, proliferate, and differentiate into memory B cells or antigen-producing plasma cells.

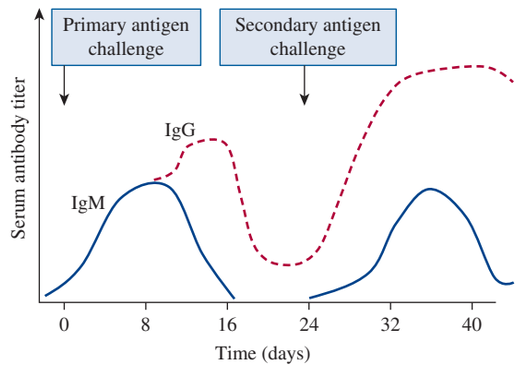

Figure 12-11. *Kinetics of humoral immune responses.* In response to primary antigen encounter, IgM is produced within several days. In response to secondary antigen encounter, IgG is produced more rapidly, and to a higher magnitude, than IgM.

on NK cells to antibodies coating target cells; and (3) receptor-mediated recognition of complement-coated foreign targets by macrophages.

In cell-mediated cytotoxicity, the CTL, iNKT, or NK effector cell binds in a specific manner to the target cell. The majority of CTLs express CD8 and recognize either foreign MHCI on the surface of allogeneic cells or antigen in association with self-MHCI (e.g., viral particles). Fig. 12-12 shows the cell-mediated CTL response. NK cell recognition of target cells is also antigen-specific because the mechanism of recognition involves binding of Fc receptors on NK cells to the Fc portion of antigen-specific antibody that coats the target cell; a process referred to as ADCC. Once the CTL or NK cells interact with the target cell, the effector cell undergoes cytoplasmic reorientation so that cytolytic granules are oriented along the side of the effector, which is bound to the target. The effector cell then releases the contents of these granules onto the target cell. The target cell may be damaged by the perforins or enzymatic contents of the cytolytic granules. In addition, CTLs induce

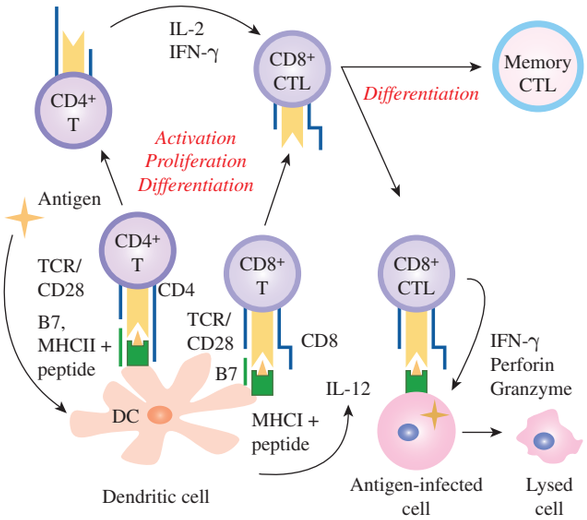

Figure 12-12. *Cellular interactions in the CTL response.* Antigen is engulfed by an APC (usually DC) and the antigenic peptide is presented to $CD4^+$ and $CD8^+$ T cells in the context of MHC II and I, respectively. $CD4^+$ T cells then become activated, proliferate, and differentiate into Th cells, which release cytokines to help $CD8^+$ T cells that had also encountered the same antigen. Especially in the presence of IL-12 produced by the DC, $CD8^+$ T cells become activated, proliferate, and differentiate into CTL that can kill other antigen-infected cells.

the target to undergo apoptosis through activation of the Fas and cytotoxic cytokine (i.e., TNF-α and lymphotoxin) pathways. Once it has degranulated, the effector cell can release the dying target and move on to kill other target cells. Notably, many of the soluble factors critical to the innate immune system are also primary effectors in the acquired immune system, including ROS, granzyme, perforin, cytokines, and chemokines, again demonstrating the interplay among the various arms of the immune system.

Inflammation

Inflammation, simply defined, refers to a complex reaction to injury, irritation, or foreign invaders characterized by pain, swelling, redness, and heat. Inflammation involves various stages, including release of chemotactic factors following the insult, increased blood flow, increased capillary permeability allowing for cellular infiltration, followed by either an acute resolution of tissue damage or persistence of the response that might contribute to fibrosis or subsequent organ failure (Serhan and Savill, 2005). It is important to emphasize that while inflammation is a natural reaction to repair tissue damage or attack foreign invaders, the process often results in destruction of adjacent cells and/or tissues. Thus, there is overwhelming evidence that inflammation plays a critical role in many diseases, including asthma, multiple sclerosis, cardiovascular disease, Alzheimer disease, bowel disorders, and cancer. In addition, inflammation exacerbates idiosyncratic reactions to drugs and other chemicals (reviewed by Ganey et al. [2004]).

Cellular Components: Macrophages, Neutrophils, ILCs, and T Cells Many of the cellular components described earlier are critical to initiation and maintenance of an inflammatory response. Major cellular contributors to an inflammatory response are macrophages, neutrophils, ILCs, and T cells. Neutrophils are often the first, and most numerous, responders to sites of insult. In response to either host- or pathogen-derived signals, neutrophils secrete chemotactic factors to recruit other pro-inflammatory cells, such as macrophages, to the area. IL-17 produced early by various sources, including NKT cells and ILCs, is a critical pro-inflammatory cytokine that rapidly induces neutrophil and macrophage influx to the area of insult (Vanaudenaerde et al., 2011). Macrophages can be activated by a variety of mechanisms at the site of insult, such as activation via TLR, pro-inflammatory cytokines, or recognition of opsonized particles by Fc receptors or complement receptors. Macrophages and neutrophils also induce apoptosis of cells in the insult area through the release of nitric oxide and other ROS, resulting in disruption of extracellular structures that compromise tissue structure and function (reviewed by Duffield [2003]). Both neutrophils and macrophages are phagocytic cells and can contribute to clearing of apoptotic cells. Later in the inflammatory response, T cells are critical for generating an adaptive immune response. T cells are attracted to the insult area by adhesion molecules and integrins, and are activated in response to antigen presented in the context of MHC, often by a DC. As described above, depending on the signals that the T cell receives from the cytokine milieu, distinct subpopulations of T cells are induced (Fig. 12-8). Chronic inflammatory states are maintained with activation and differentiation of Th2 and Th17 cells, which drive chronic eosinophilic and neutrophilic inflammation, respectively (Jutel and Akdis, 2011). Th9 and Th22 cells also likely contribute to chronic inflammation, but their roles are not yet completely understood.

Of all Th subsets, Th17 cells have certainly been shown to play a critical role in inflammation (Kimura and Kishimoto, 2011). In contrast to cells involved in the innate response (NK or NKT cells, γδ T cells, or other ILCs) that produce IL-17, Th17 cells are part of the adaptive immune response, and produce IL-17, IL-22, and TNF-α (Vanaudenaerde et al., 2011). They are induced in the presence of IL-6 and TGF-β, conditions that are unfavorable for Tregs, thereby exacerbating the pro-inflammatory response through suppression of Treg differentiation and promotion of chronic neutrophilic infiltration (Awasthi and Kuchroo, 2009). Th17 cells are defined by the expression of retinoid-related orphan receptors RORγ and RORα. Interestingly, Th17 cells also express high levels of aryl hydrocarbon receptor (AhR) (Veldhoen et al., 2008), providing an additional cellular target for immune modulation by AhR ligands (see the section "Halogenated Aromatic Hydrocarbons").

There are several other soluble factors that contribute to inflammation that warrant discussion. In addition to ROS that are released from both macrophages and neutrophils to compromise membrane integrity, a plethora of cytokines and chemokines contribute to the inflammatory process. As mentioned in the section "Innate Immunity," some pro-inflammatory cytokines (IL-1β and IL-18) are produced in a mature form as a result of the activation of the inflammasome (Martinon et al., 2009). In fact, it has been demonstrated that inflammation as a result of disease (i.e., influenza) or toxicity (i.e., silicosis) depends on inflammasome activation (Cassel et al., 2008; Ichinohe et al., 2009). An additional discussion regarding the role of the inflammasome in immune responses to inhaled particles is provided in "Inhaled Substances." The actions of various pro-inflammatory cytokines include inducing fever or activating T cells and macrophages (IL-1); stimulating B- or T-cell proliferation (IL-6); inducing neutrophilia (IL-17); and increasing vascular permeability or inducing apoptosis (TNF-α). Many pro-inflammatory cytokines also induce acute-phase proteins, such as C-reactive protein. C-reactive protein binds to several ligands, including phosphatidylcholine on the membranes of cells, Fc receptors, and C1q (part of the complement C1 complex), which activates the classical complement cascade (reviewed by Marnell et al. [2005]). Complement participates in inflammation through inappropriate and sustained

activation of the cascade, ultimately leading to destruction of cells through the MAC (Fig. 12-3). Furthermore, complement fragments, such as C3a and C5a, act as chemotactic factors to recruit other phagocytic cells to sites of insult (macrophages, neutrophils, eosinophils, or mast cells) or induce degranulation (basophils, eosinophils, or mast cells) (Dunkelberger and Song, 2010). Finally, prostaglandins and other eicosanoids possess various pro-inflammatory actions, including increased blood flow and pain (prostaglandin E2), increase in vascular permeability (prostacyclin I2), and stimulation of endothelial inflammatory responses (thromboxane A2) (reviewed by Ricciotti and FitzGerald [2011]). Prostaglandins contribute to hyperalgesia and it is for this reason that cyclooxygenase-2, which converts arachidonic acid to other bioactive prostaglandins, is an attractive therapeutic target to reduce inflammation and pain (see the section "Therapeutic Drugs: Anti-inflammatory Drugs").

As mentioned above, it is undisputed that chronic inflammation plays a critical role in many disease states, including asthma, multiple sclerosis, cardiovascular disease, Alzheimer disease, bowel disorders, and cancer. Chronic inflammation could result in high circulating levels of pro-inflammatory cytokines, complement fragments, prostaglandins, and thromboxanes. An inflammatory cascade can be established because many of these mediators induce expression of others (i.e., TNF-α induces expression of IL-1 and IL-6 or complement fragment C3a causes chemotaxis of phagocytic cells). Moreover, the sustained presence of pro-inflammatory cytokines could exacerbate ROS production from neutrophils and macrophages. As seen in the next section, the underlying pro-inflammatoryresponse also plays a critical role in immune-mediated disease.

Immune-Mediated Disease

Recall that the purpose of the immune system is to preserve the integrity of the individual from disease states, whether infectious, parasitic, or cancerous, through both cellular and humoral mechanisms. In so doing, the ability to distinguish self from nonself plays a predominant role. However, situations arise in which the individual's immune system responds in a manner producing tissue damage, resulting in a self-induced disease. These disease states fall into two categories: (1) hypersensitivity, or allergy, and (2) autoimmunity. Hypersensitivity reactions result from the immune system responding in an exaggerated or inappropriate manner after repeated exposure to the offending antigen. These reactions have been subdivided by Coombs and Gell (1975) into four types, which represent four different mechanisms leading to tissue damage. In the case of autoimmunity, mechanisms involve a break down in self-recognition resulting in the production of autoreactive antibodies and/or TCRs recognizing self-antigens as nonself, ultimately culminating in tissue damage and disease.

Hypersensitivity

Classification of Hypersensitivity Reactions One characteristic common to all four types of hypersensitivity reactions is the necessity of prior exposure leading to sensitization in order to elicit a reaction upon subsequent challenge. In the case of Types I, II, and III, prior exposure to antigen leads to the production of allergen-specific antibodies (IgE, IgM, or IgG) and, in the case of Type IV, the generation of allergen-specific memory T cells. Fig. 12-13 illustrates the mechanisms of hypersensitivity reactions as classified by Coombs and Gell (1975). Although not completely understood, regulation of Ig production is dependent in part on the characteristics of the antigen, the genetics of the individual, and environmental factors. The mechanisms of antibody production in hypersensitivity reactions are identical to those described earlier

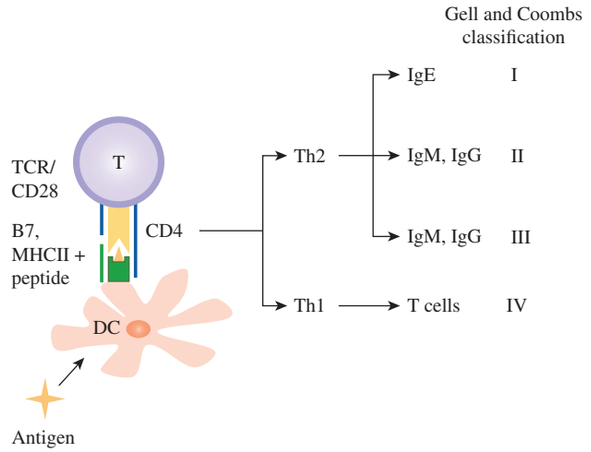

Figure 12-13. *Overview of classification of hypersensitivity reactions.* Hypersensitivity reactions are mediated via T cells and antibody production.

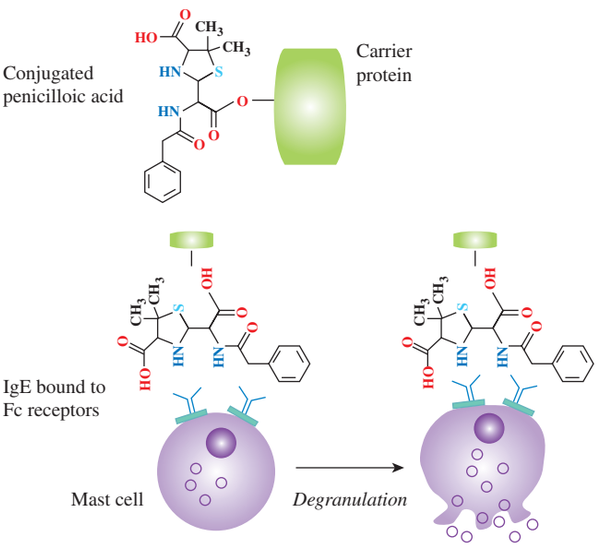

Figure 12-14. *Type I hypersensitivity reaction.* Metabolized penicillin is a hapten that conjugates with a protein. The conjugated hapten crosslinks IgE antibodies on mast cells. IgE crosslinking causes mast cell degranulation, releasing histamine and other pro-inflammatory mediators.

in the chapter (Fig. 12-10). A brief description of the four types of hypersensitivity reactions is presented below.

Type I (Immediate or IgE-Mediated Hypersensitivity) Using penicillin as an example, Fig. 12-14 depicts the major events involved in a Type I hypersensitivity reaction (what most people think of as "allergy" and is clinically referred to as "atopy"). Sensitization occurs as the result of dermal exposure to antigens or by exposure to antigens through the respiratory or gastrointestinal tract. Most people would mount an IgM, IgG, or IgA immune response to these antigens and clear them without causing any allergic symptoms. It is unclear why these antigens become allergens in certain individuals who respond by mounting an IgE immune response instead, but the mechanism appears to involve genetic and/or environmental determinants and likely some type of triggering event (e.g., acute pathogen exposure and emotional stress). IgE production is highest in lymphatic tissues that drain sites of exposure (i.e., tonsils, bronchial lymph nodes, and intestinal lymphatic tissues, including Peyer's patches) and is low in

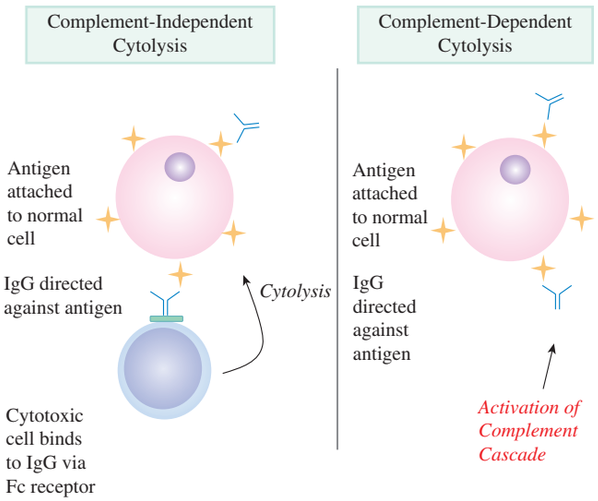

Figure 12-15. *Type II hypersensitivity reactions.* In complement-independent cytolysis, antigen becomes attached to a normal cell, which can be recognized by IgG. A cell capable of cytolysis (CTL, NK cell) binds to IgG via its Fc receptor and kills the antigen-coated cell. In complement-dependent cytolysis, antigen becomes attached to a normal cell, which can be recognized by IgG. Complement gets activated by the classical pathway (antigen–antibody complexes).

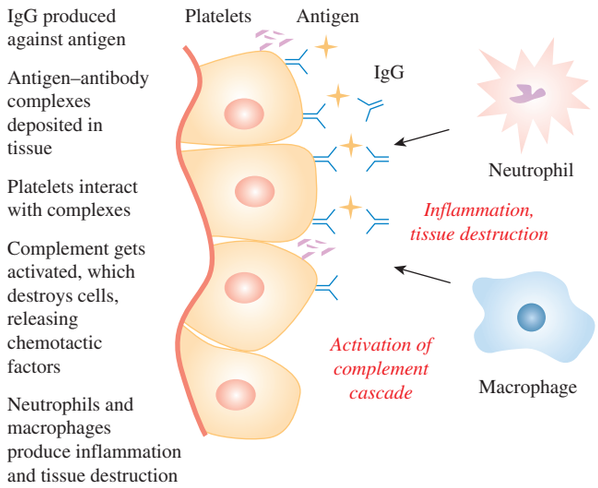

Figure 12-16. *Type III hypersensitivity reactions.* IgG is produced against an antigen and antigen–antibody complexes form, which can become deposited in tissue. Complement gets activated by the classical pathway (antigen–antibody complexes) and platelets also interact with complexes. Following complement-mediated cytolysis, released chemotactic factors attract neutrophils and macrophages, causing additional inflammation and tissue damage.

the spleen. Compared to other Igs, IgE has a low serum concentration and a short serum half-life (Table 12-6). Once produced, soluble IgE not only binds to local tissue mast cells, but also enters the circulation, where it binds to circulating mast cells, basophils, and tissue mast cells at distant sites. Once an individual is sensitized, reexposure to the antigen results in binding to IgE on local mast cells and degranulation with the release of preformed mediators and cytokines that recruit and activate circulating eosinophils, basophils, macrophages, and neutrophils leading to the synthesis and release of more cytokines and of leukotrienes and thromboxanes. These mediators promote vasodilation, bronchial constriction, and inflammation. Clinical manifestations can vary from urticarial skin reactions (wheals and flares) to signs of hay fever, including rhinitis and conjunctivitis, to more serious diseases, such as asthma and potentially life-threatening anaphylaxis. These responses may begin within minutes of reexposure to the offending antigen; therefore, Type I hypersensitivity is often referred to as immediate hypersensitivity.

Type II (Antibody-Dependent Cytotoxic Hypersensitivity) Type II hypersensitivity is IgG or IgM-mediated. A foreign antigen attached to the surface of a cell or tissue may mediate the antibody response. Conversely, an antibody response could be mediated by an autoantibody due to a breakdown in tolerance and the resulting response would be part of an autoimmune disease (e.g., autoimmune hemolytic anemias and Goodpasture syndrome). Fig. 12-15 shows the mechanisms of action for complement-independent and complement-dependent cytotoxic reactions. Tissue damage may result from the direct action of cytotoxic cells, such as macrophages, neutrophils, or eosinophils, linked through the Fc receptor to antibody-coated target cells (complement-independent) or by antibody-induced activation of the classic complement pathway. Complement activation may result in C3b binding to the target cell surface with C3b acting as a recognition site for effector cells. Alternatively, the MAC may be bound to the target cell surface, resulting in direct cell lysis.

Type III (Immune Complex–Mediated Hypersensitivity) Type III hypersensitivity reactions also involve IgG or IgM. The distinguishing feature of Type III is that, unlike Type II, in which Ig production is against specific cellular or tissue-associated antigen, Ig production is against soluble antigen in the serum (Fig. 12-16). This allows for the formation of circulating immune complexes composed of a lattice of antigen and Ig, which may result in widely distributed tissue damage in areas where immune complexes are deposited. The most common location is the vascular endothelium in the lung, joints, and kidneys. The skin and circulatory systems may also be involved. Pathology results from the inflammatory response initiated by the activation of complement. Macrophages, neutrophils, and platelets attracted to the deposition site contribute to the tissue damage. As with Type II hypersensitivity, responses similar to Type III hypersensitivity can be induced in autoimmune diseases due to autoantibodies directed against soluble antigens such as double-stranded DNA or small nuclear proteins as seen with systemic lupus erythematosus (SLE). In addition, antibody responses directed to protein therapeutics/biologics can lead to the formation of immune complexes with the drug and, if the appropriate size, can result in Type III hypersensitivity responses. These responses can manifest either as infusion reactions following dosing due to complement activation and cytokine release, loss of platelets, or tissue damage (Krishna and Nadler, 2016).

Type IV (Cell-Mediated Hypersensitivity) Type IV, or DTH responses, can be divided into three classes: contact hypersensitivity, tuberculin-type hypersensitivity, and hypersensitivity pneumonitis. The following discussion is focused on contact hypersensitivity using the classical example of contact hypersensitivity seen following poison ivy exposure. Contact hypersensitivity is initiated by topical exposure, and the associated pathology is primarily epidermal. It is characterized clinically by an eczematous reaction at the site of allergen contact and, like Type I through III responses, consists of two phases: sensitization and elicitation. However, in this case sensitization is the result of the development of activated and memory T cells as opposed to antibody production (Figs. 12-17 and 12-18). Sensitization occurs when a hapten

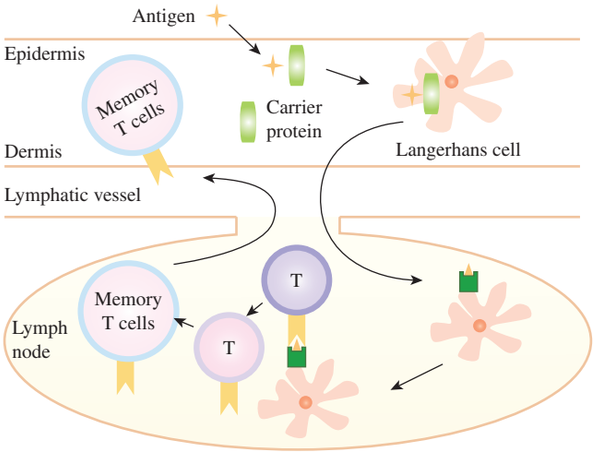

Figure 12-17. *Type IV hypersensitivity sensitization.* A hapten permeates the epidermis and forms a complex with a carrier protein. The conjugated hapten gets engulfed by Langerhans DCs, which migrate to the lymph node and present antigen to $CD4^+$ T cells in the context of MHCII. $CD4^+$ T cells activate, proliferate, and differentiate into Th cells and memory T cells.

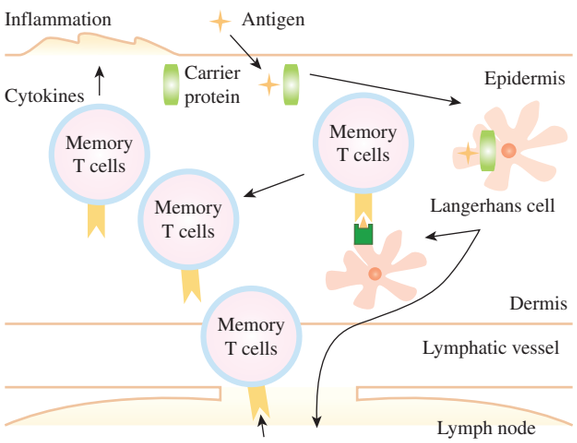

Figure 12-18. *Type IV hypersensitivity elicitation.* Upon secondary exposure to the hapten, Langerhans DCs either migrate to the lymph node or directly present antigen to memory T cells. Memory T cells become activated and produce cytokines to stimulate pro-inflammatory cytokine release from other cell types, such as keratinocytes.

penetrates the epidermis and forms a complex with a protein carrier. The hapten–carrier complex is processed by Langerhans DCs that migrate out of the epidermis to the local lymph nodes. There, the APC presents the processed antigen to $CD4^+$ Th cells, leading to clonal expansion and the generation of memory T cells including memory $CD8^+$ CTL, which appear to play a major role in the elicitation phase.

Upon secondary contact, Langerhans DCs present the processed hapten–carrier complex to memory $CD8^+$ CTL in either the skin or the lymph nodes. These activated T cells then secrete cytokines that bring about further proliferation of T cells and generation of CTLs, as well as increased expression of adhesion molecules on the surface of keratinocytes and endothelial cells in the dermis. Both the expression of adhesion molecules and the secretion of pro-inflammatory cytokines by T cells and keratinocytes facilitate the recruitment of inflammatory cells into the skin, resulting in erythema and the formation of papules and vesicles. In addition and under certain circumstances, intracellular proteins can be modified by lipid-soluble chemicals that might readily cross the cell membrane. These cells then present modified peptides on their cell surface in conjunction with MHCI molecules. $CD8^+$ cytotoxic T cells recognize these foreign peptides and cause tissue damage by either direct cytotoxic action (CTL) or the secretion of cytokines that further promote the inflammatory response.

Table 12-7

Sites of Autoimmune Reactions

SITE/TARGET	DISEASE EXAMPLE
Nuclei—antibodies against DNA or histones	Systemic lupus erythematosus
Red blood cells	Hemolytic anemia
Striated muscle—cholinergic receptors	Myasthenia gravis

Autoimmunity Autoimmune disease occurs when the reactions of the immune system are directed against the body's own tissues, and, as with hypersensitivity, is characterized by a genetic susceptibility. Autoimmune diseases may be tissue-specific, in which the damage is associated with a specific type of tissue or a specific organ, or tissue-nonspecific, in which the signs and symptoms are associated with several organs and tissues. The targets from the perspective of the primary sites of tissue damage in autoimmune disease are many and varied (Table 12-7). Both humoral immunity and CMI can be involved as effector mechanisms in causing the damage in autoimmune conditions. The terms "hypersensitivity" and "autoimmunity" are often confused and are certainly interrelated. Based on their definitions, a hypersensitivity response can be a mechanism by which an autoimmune disease is produced.

In the section on hypersensitivity presented above, two mechanisms by which host tissues are damaged by the host's own immune system were discussed (Types II and III), resulting in autoimmune-like disease. It is important to emphasize that in the case of hypersensitivity reactions, unaltered self-antigens are not the target of the immune mechanisms, but damage occurs to cells bearing a hapten on their membranes, or nonspecifically to innocent bystander cells in close proximity to antigen–antibody complexes that activate the complement cascade. For example, damage produced in autoimmune Goodpasture disease is similar to that induced by Type III hypersensitivity reactions in the lung due to trimellitic anhydride (TMA) exposure (see the section "Acid Anhydrides"). Although the resulting pathology may be very similar for autoimmune reactions and hypersensitivity, the precipitating mechanisms for true autoimmune disease are distinct from hypersensitivity. Specifically, in cases of autoimmunity, self-antigens are the target of the immune response, and in the case of chemical-induced autoimmunity, the disease state is induced by a modification of host tissues or immune cells by the chemical and not the chemical acting as an antigen/hapten as in hypersensitivity reactions.

Mechanisms of Autoimmunity As discussed earlier, the rearrangement and recombination of the genes that comprise Ig and TCR result in tremendous diversity in the potential antigen recognition of B cells and T cells, respectively. Ideally, during development those lymphocytes recognizing self-antigens will largely be deleted by negative selection as central tolerance is established. Autoreactive clones that escape central tolerance and migrate to

the periphery are normally controlled by peripheral tolerance mediated by various mechanisms that ultimately induce anergy or clonal deletion. For autoimmune disease to occur, an autoreactive clone must escape central tolerance, pass into the periphery, and bind with specificity to its self-antigen; then mechanisms of peripheral tolerance must fail, and the autoreactive clone must induce a detrimental immunological response. Clearly, induction of autoimmunity is multifaceted and likewise has been associated with several mechanisms primarily related to insufficient peripheral tolerance. Conversely, defects in central tolerance are rarely encountered. However, an example of autoimmunity due to defective central tolerance is the disease autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy, which results from a defective transcriptional regulator called autoimmune regulator (AIRE). For the negative selection process in the thymus, AIRE induces the expression of a wide variety of self-antigens normally found in the periphery. Loss of AIRE results in release of autoreactive T cells to the periphery. Several mechanisms have been associated with the breakdown of peripheral tolerance and prime events for the onset of autoimmune disease. These mechanisms include inflammation; molecular mimicry by pathogen antigens; inherent defects in T or B cells including regulatory subsets, APCs, cytokines, or complement; and epitope spreading. For example, increasing evidence supports a potential breakdown of peripheral tolerance during an inflammatory response, which may be mediated by the inappropriate maturation of immature DCs that process both pathogenic antigens and self-antigens released during the inflammatory response. Self-antigens could then be presented to naive autoreactive T cells via MHC. With molecular mimicry, a pathogen presents epitopes that resemble those on self-antigens, and because the pathogen will induce a strong inflammatory response, peripheral tolerance may be overridden. Additionally, interference of normal immune regulation by Tregs or Bregs could create an environment conducive to autoimmune disease. Finally, epitope spreading may occur during an immune response due to tissue damage and the release of new epitopes that were hidden either because they were sequestered from the immune system or their expression levels were insufficient to induce negative selection or peripheral tolerance mechanisms.

Effector mechanisms involved in autoimmune disease can be the same as those described earlier for Types II and III hypersensitivity or, in the case of pathology associated with solid tissues, including organs, they may involve $CD8^+$ CTL. Tissue damage associated with CTL may be the result of direct cell membrane damage and lysis, or the result of cytokines produced and released by the T cell. TNF-β (lymphotoxin) has the ability to kill susceptible cells, and IFN-γ may increase the expression of MHCI on cell surfaces, making them more susceptible to $CD8^+$ cells. Cytokines may also be chemotactic for macrophages, which can cause tissue damage directly or indirectly through the release of pro-inflammatory cytokines. As is the case with hypersensitivity reactions, autoimmune disease is often the result of more than one mechanism working simultaneously.

Developmental Immunology

A sequential series of carefully timed and coordinated developmental events, beginning early in embryonic/fetal life and continuing through the early postnatal period, is required to establish a functional immune system in all mammals, including humans (Fig. 12-19). The immune system develops initially from a population of pluripotent HSCs that are generated early in gestation from uncommitted mesenchymal stem cells in the intraembryonic splanchnopleure surrounding the heart. This early population of HSCs gives rise to all circulating blood cell lineages, including cells of the immune system, via migration through an orderly series of tissues, and a dynamic process that involves continual differentiation of lineage-restricted stem cells. Lymphoid-hematopoietic progenitor cells are established via the migration of these cells from intraembryonic mesenchyme to fetal liver and fetal spleen, and ultimately, the relocation of these cells in late gestation to bone marrow and thymus. The latter two organs are the primary sites of lymphopoiesis and appear to be unique in providing the microenvironment factors necessary for the development of functionally competent immune cells. These lineage-restricted stem cells expand to form a pool of highly proliferative progenitor cells that are capable of continual renewal of short-lived functional immunocompetent cells (Fig. 12-2), and that ultimately provide the necessary cellular capacity for effective immune responsiveness, and the necessary breadth of the immune repertoire (Good, 1995).

It is important to recognize that immune system development does not cease at birth, and that immunocompetent cells continue to be produced from proliferating progenitor cells in the bone marrow and thymus (Fig. 12-2). Mature immunocompetent cells leave these primary immune organs and migrate via the blood to the secondary immune organs: spleen, lymph nodes, and mucosal lymphoid tissues. Because birth occurs at various stages of fetal maturity in different species, the significance of parturition as a landmark in the development of the immune system can vary from species to species (Holsapple et al., 2003). As such, direct comparison of immune functional development between humans and animals is complicated by differences in the maturity of the immune system before and after parturition. This difference has been linked to the length of gestation (Holladay and Smialowicz, 2000), in that animals with short gestation periods (e.g., mice, rats, rabbits, and hamsters) have relatively immature immune systems at birth compared to humans. The onset of functional immune competence depends on the specific parameter being measured, and varies across species with striking differences noted between rodents and humans (Holsapple et al., 2003). The immune system of children continues to develop postnatally until 5 to 12 years of age (Miyawaki et al., 1981). Exposure to specific antigens during the perinatal period results in a rapidly expanding accumulation of lymphocyte specificities in the pool of memory cells in secondary lymphoid tissues. As thymic function wanes and thymocytes are no longer produced in that tissue, it is this pool of memory B and T cells that maintains immune competence for the life of the individual. Senescence of immunity is associated with reductions in both innate and acquired immune responses to antigens during the last quartile of life. This failure of the immune response is due, in part, to a continual reduction in the production of newly formed cells, and to the decreased survival of long-lived memory cells in lymphoid tissues. The concept of immune senescence is discussed further below.

One feature of the developing immune system that clearly distinguishes it from the mature immune system, especially during gestation, is the role played by organogenesis. Defects in the development of the immune system due to heritable changes in the lymphoid elements have provided clinical and experimental examples of the devastating consequences of impaired immune development (Rosen et al., 1995). Therefore, the effects of chemicals on the genesis of critical immune organs in the developing fetus may be more important than effects on these tissues after having been populated by hematopoietic and lymphoid cells. However, a chemical that induces this kind of developmental structural abnormality in the fetus would legitimately be classified as a teratogen, prompting the question as to how many known teratogens would have an impact on organs essential to the normal functioning of the immune system.

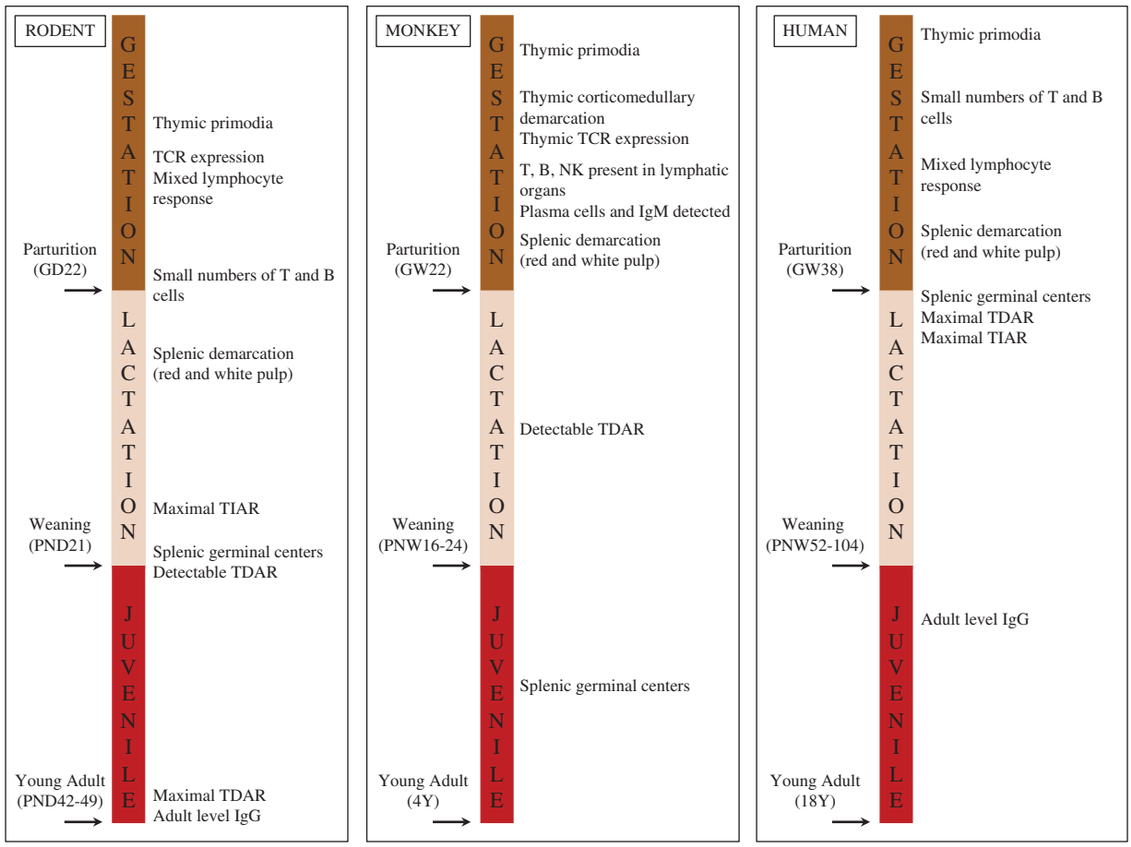

Figure 12-19. *Developmental immunology.* Comparison of major developmental milestones in human, monkey, and mouse. Species-specific timelines for gestation, lactation, and juvenile stages are also presented. GD, gestational day; GW, gestational week; PND, postnatal day; PNW, postnatal week.

At the other end of the spectrum from the development of the immune system during gestation and the perinatal period is the status of the immune system in the aging population. Unlike the developing immune system, there have been very few studies that have addressed the impact of specific xenobiotics on the aging immune system. Nonetheless, it is known that the immune system of older people is usually perceived as declining in fidelity and efficiency with age resulting in an increased susceptibility to infectious diseases and pathological conditions relating to inflammation (e.g., cardiovascular disease and Alzheimer's Disease) or autoreactivity (e.g., rheumatoid arthritis, RA) (Caruso et al., 2009). Immune senescence has been defined as the impairment in immunity as a result of age-associated changes in function in a variety of cell types. It is a phenomenon of decreased function, involving changes in both innate and adaptive immunity, and a disbalance between the two arms (Pawelec et al., 2010). Virtually, all components of the immune system are affected (Ongradi and Kovesdi, 2010). The decline in the B-cell compartment is responsible for the decreased effectiveness of vaccines in older people, and the decline in immune surveillance (e.g., the T-cell compartment and NK-cell function) is associated with an increased incidence in malignancy. Additionally, aging has been associated with a shift from the Th1 to the Th2 cytokine profile in response to immune stimulation, and the overproduction of Th2 cytokines could augment B-cell production of autoreactive antibodies. Studies in humans and mice have shown that TLR expression and function decline with age resulting in the decreased production of pro-inflammatory cytokines and chemokines. From a mechanistic standpoint, a number of factors have been proposed as contributing to the onset and severity of immune senescence including the accumulation of damage to lymphocytes by oxidative stress, persistent microbial infections with immunosuppressive viruses that establish latency, such as cytomegalovirus and Epstein–Barr virus, and lifestyle factors such as smoking, alcohol use, and poor nutrition. An improved understanding of immune dysfunction in human aging will increase the probability of discovering means to restore appropriate function and alleviate the burden of infectious disease later in life (Ongradi and Kovesdi, 2010).

Neuroendocrine Immunology

There is overwhelming evidence that cytokines, neuropeptides, neurotransmitters, and hormones, as well as their receptors, mediate interactions between the CNS, endocrine, and immune systems. Because receptors for neuropeptides, neurotransmitters, and hormones are present on lymphoid cells, some chemicals exert their immunomodulatory effects indirectly on the immune system by acting to modulate the activity of the nervous or endocrine systems. In addition, immune cells secrete peptide hormones and neurotransmitters, which can have autocrine (immune system) and paracrine (endocrine and nervous systems) effects. Similar to the complexity of the cytokine network, the effects of various hormones and neurotransmitters are too vast to discuss here. However, it is evident, even from this brief overview of the immune system and its potential interaction with other biological systems, that immune responses are complex processes involving multiple cell types and mediators (reviewed by Kaplan et al. [2015]).

ASSESSMENT OF IMMUNOLOGIC INTEGRITY

For many years, it has been widely established that xenobiotics can exert significant effects on the immune system as evidenced by changes in circulating and lymphoid organ-associated leukocyte number, proliferative capacity, and in effector functions including defense against a broad array of bacterial, parasitic, and viral pathogens. During the establishment of the subdiscipline of immunotoxicology, a significant emphasis was placed on the development of a standardized battery of tests to evaluate immune competence. Among the unique features of the immune system is the ability of immune cells to be removed from the body and to function in vitro. This unique quality makes it possible to comprehensively evaluate the actions of xenobiotics on the immune system employing in vivo, ex vivo, and in vitro approaches to dissect the cellular, biochemical, and molecular mechanisms of action of xenobiotics. While standard toxicological endpoints such as organ weights, cellularity, and enumeration of cell subpopulations are important components in assessing when an agent is capable of altering the immune system, by far the most sensitive indicators of immunotoxicity are the tests that induce the various cell types within the immune system to respond functionally to exogenous stimuli (White, 1992; Descotes, 2004). Employing such a battery of functional assays whereby different cell types can be evaluated not only for their effector functions, but also in certain cases for their ability to participate as accessory cells in an immune response can provide important mechanistic information concerning which cell type(s) within the immune system are, in fact, targeted by a xenobiotic. This section focuses on selected in vivo, ex vivo, and in vitro tests currently used for evaluating immunotoxicity, as well as models and approaches that can be utilized for elucidation of the mechanism of action.

The current state-of-the-science of immunotoxicity testing can be found in *Immunotoxicology Strategies for Pharmaceutical Safety Assessment* by Herzyk and Bussier (1st edition, 2008) or in *Immunotoxicity Testing: Methods and Protocols (Methods in Molecular Biology)* by Dietert (2010).

General Assessment

Central to any series of studies evaluating immune competence is the inclusion of standard toxicological studies, because any immunologic finding should be interpreted in conjunction with effects observed on other target organs. Standard toxicological studies that are usually evaluated include body and selected organ weights, general observations of overall animal health, selected serum chemistries, hematologic parameters, and status of the bone marrow (ability to generate specific colony-forming units). In addition, histopathology of lymphoid organs, such as the spleen, thymus, and lymph nodes, may provide insight into potential immunotoxicants. General guidelines for the histopathological examination of each of these lymphoid organs have been reviewed (Elmore, 2010).

Because of the unique nature of the immune system, there are several experimental approaches that may be taken to assess immunotoxicity and to evaluate the mechanisms of action of xenobiotics. These are depicted in Fig. 12-20 and vary with respect to in vivo or in vitro exposure, immunologic challenge (i.e., the stimulus employed to induce an immune response), or immunologic evaluation (immune assay). As an example, Fig. 12-20(b) is an ex vivo assay in which xenobiotic exposure and antigen challenge occur in vivo and the immune response is evaluated in vitro. In contrast, as depicted in Fig. 12-20(c), splenocytes can be isolated after in vivo

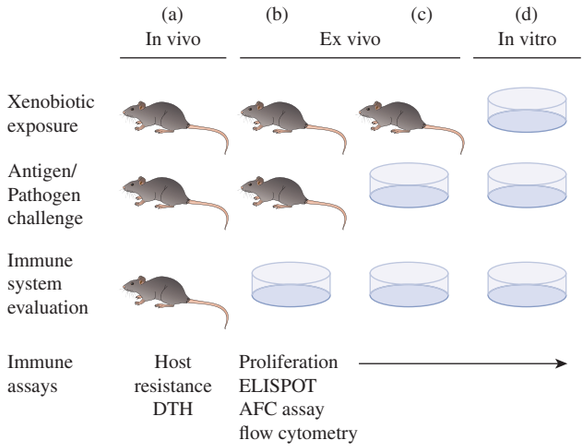

Figure 12-20. *Approaches for assessing the immunotoxicity of xenobiotics.* The ability to stimulate immune cells in vitro allows for much flexibility in the assessment of immunotoxicity of xenobiotics.

treatment with a xenobiotic, sensitized with an antigen in vitro and evaluated in vitro; or as depicted in Fig. 12-20(d), splenocytes can be removed from a naive (untreated) animal, exposed to a xenobiotic and antigen in vitro, and evaluated in vitro. If splenocytes are sensitized in vitro with sheep red blood cells (sRBCs) to generate antibody forming cells (AFCs), this is known as the Mishell–Dutton assay (Mishell and Dutton, 1967).

Functional Assessment

Innate Immunity As described earlier, innate immunity encompasses all those immunologic responses that are not induced through antigen receptors (i.e., TCR or BCR) and for which there is limited immunological memory. These responses include phagocytosis of pathogens and release of ROS as a killing mechanism by macrophages, neutrophils, and monocytes; recognition of tumor cells by NK cells; and the lytic activity of the components of the complement cascade.

To evaluate phagocytic activity in vitro or ex vivo, plate-based or flow cytometric methods can be used to measure the amount of fluorophore-labeled foreign matter engulfed by phagocytic cells. For example, phagocytic cells, isolated from tissues including blood, peritoneal cavity fluid, and bronchial alveolar lavage fluid that adhere to tissue culture plates or whole blood containing monocytes and granulocytes, are incubated with fluorophore-labeled particles such as opsonized *Escherichia coli* or polystyrene beads in the absence or presence of additional stimuli (e.g., mitogens such as phorbol myristate acetate (PMA) or chemotactic peptide *N*-formyl-methionine-leucine-phenylalanine [fMLP]). To quantify the overall degree of fluorescence or the number of particles engulfed, cell samples are then analyzed by a microplate fluorimeter, fluorescent microscopy, or flow cytometry.

During phagocytosis, ROS are generated in response to soluble antigens to kill the pathogen. There are several in vitro or ex vivo methods available to measure this functional response, termed respiratory burst, that are based on quantifying the production of intracellular or extracellular ROS such as free oxygen radicals, nitric oxides, or hydrogen peroxide. These methods, which can be plate- or flow cytometry–based, quantify the fluorescence elicited by oxidation of a fluorogenic substrate. As with the phagocytosis assays, phagocytic adherent cells isolated from tissues including blood, peritoneal cavity fluid, and bronchial alveolar lavage fluid or

whole blood, which contains monocytes and neutrophils, are incubated with a substrate (e.g., dihydrorhodamine 123 or 6-carboxy-2,7-dichlorodihydrofluorescien diacetate) that is internalized. The cells are then incubated with a respiratory burst stimulator such as phorbol esters, opsonized *E. coli*, or zymosan and the amount of fluorescence is recorded using a microplate fluorimeter, or by flow cytometry that also allows for the identification of the cell type(s) affected (Freebern et al., 2013).

Phagocytosis can also be assessed in vivo. An older method involved intravenous injection of radiolabeled sRBCs (^{51}Cr-sRBCs), which are removed from the circulation by tissue macrophages and sequestered for degradation in organs such as the liver, spleen, lymph nodes, lung, and thymus. Clearance of the ^{51}Cr-sRBCs is monitored by sampling the peripheral blood. After steady state has been attained, organs are assayed using a gamma counter to assess uptake of the ^{51}Cr-sRBCs. Similar to in vitro methods, newer methods to assess in vivo phagocytosis involve injection of fluorophore-labeled particles, including nanoparticles or bacteria (Tartaro et al., 2015).

When phagocytic cells encounter antigens, especially those associated with bacteria or a virus, they undergo activation, which is induced, in part, through interactions with TLRs. Extracellular antigens are processed and presented in association with MHCII, while intracellular antigens are processed and presented in association with MHCI, as described in the section "Antigen Processing." Concomitant with antigen encounter by the phagocyte, there is an increase in the expression of MHCI and/or MHCII as well as the costimulatory molecules CD80/CD86. The simultaneous increase in MHC molecules in combination with CD80 and CD86 is critically important in order for the phagocytic cell to drive T-cell effectors ($CD4^+$ and $CD8^+$ T cells). To further assess phagocytic cell function and the influence of an immunotoxicant, the upregulation of MHCI and/or MHCII and CD80 and CD86 can be readily quantified by flow cytometry (see the section "Flow Cytometric Analysis") after the activation of phagocytic cells, primarily those of the monocytic lineage. These measurements are especially informative when performed in combination with cell surface markers that are capable of identifying monocytic lineage subpopulations such as tissue macrophages, conventional DC, and plasmacytoid DC because they provide information on whether the immunotoxicant interferes with the activation and/or differentiation of the phagocytic cell and its antigen presenting capability. The types of macrophages and DCs, their hematopoietic origin, and a general discussion of the different assays used to assess their functional status have been reviewed (Barnett and Brundage, 2010; Satpathy et al., 2012).

Evaluation of the ability of NK cells to lyse tumor cells is achieved using species-specific tumor cell lines (e.g., murine YAC-1 or human K562 cell line) as a tumor target for an in vitro cytotoxicity assay. Tumor cells are radiolabeled with ^{51}Cr and incubated in specific effector-to-target ratios with splenocytes or peripheral blood mononuclear cells (PBMCs) from xenobiotic-exposed and nonexposed animals. During an incubation step, NK cells (effectors) lyse the ^{51}Cr-tumor cells, releasing ^{51}Cr into the supernatant. At the end of the incubation, culture plates are centrifuged and the supernatant is removed and counted by a gamma counter. After correcting for spontaneous release (which should be less than 10%), specific release of ^{51}Cr is calculated for each effector-to-target ratio and compared to the specific release from control animals. To avoid the use of radionucleotides, a number of flow cytometry–based assays have been developed utilizing fluorescent stains to identify live and dead target cells. One such assay involves the co-culture of NK cells with targets cells that have been stained with the fluorescent green dye 3,3′- dioctadecyloxacarbocyanine perchlorate (DiO) (Kane et al., 1996). Utilizing DiO allows for readily discriminating between target and nontarget cells while propidium iodide is used to distinguish between live and dead cells. The various methods for NK assays used in immunotoxicity testing have been reviewed (Li, 2010).

More recently, NK cell activity is also assessed by quantifying the expression of lysosome-associated membrane protein-1 (LAMP-1, CD107a). As degranulation of NK cells occurs, secretory lysosomes are released and CD107a is transported to the surface of the NK cells. Once on the surface, CD107a can be detected by antibody binding and allow for the identification of activated NK cells, thus serving as a biomarker for NK cell functional activity. Specifically, human or nonhuman primate (NHP) NK cells (PBMC or whole blood) are co-cultured with either K562 cells or PMA and ionomycin and the percentage of CD3, CD56/CD159 (NK cell surface markers), and CD107a positive cells are quantified by flow cytometry.

Acquired Immunity: Humoral The AFC assay is a sensitive indicator of immunologic integrity for several reasons. It is a test of the ability of the host to mount an antibody response to a specific antigen. When a T-cell-dependent antigen (an antigen that requires T cells to help B cells make antibody) like sRBC is used, this response, referred to as the T-cell-dependent antibody response (TDAR), requires the coordinated interaction of several different immune cells: APC (macrophages and DCs), T cells, and B cells. Therefore, functional impairment of any one of these cell types (e.g., antigen processing and presentation, cytokine production, proliferation, or differentiation) can alter the ability of B cells to produce antigen-specific antibodies. Other antigens, termed T-cell-independent antigens, such as dinitrophenyl-Ficoll or trinitrophenyl-LPS, can also be used that bypass the requirement for accessory T-cell help in eliciting antibody production by B cells, and is thus termed a T-cell-independent antibody response (TIAR). Although the AFC assay in response to sRBC was developed in rodents almost half a century ago, its sensitivity in identifying immunotoxicants has resulted in worldwide application for the purpose of hazard identification, which extends to present day (see the section "Historical Perspective on Regulatory Guidance in Immunotoxicology"). Indeed, an overview of the TDAR to sRBCs was described as the "gold standard" for evaluating the potential adverse effects of xenobiotics on the immune system (White et al., 2010).

A standard AFC assay involves immunizing control and xenobiotic-exposed mice either by intravenous or intraperitoneal injection with sRBCs. The antigen is taken up in the spleen and an anti-sRBC antibody response is induced. In the mouse, the peak day of antibody production is 4 days after immunization. Historically, the antibody response has been quantified by enumerating the number of plasma cells (also known as AFCs or ASCs) present in the spleen that are secreting anti-sRBC antibodies. This can be accomplished by removing the spleen and making a spleen cell suspension, which is then mixed with sRBC, complement, and melted agar. This mixture is poured onto a petri dish and covered with a cover slip. After the agar solidifies, the petri dishes are incubated for 3 hours at 37°C. B cells that have been appropriately activated by the antigen and have differentiated into plasma cells during the 4 days post antigen immunization are now actively secreting large quantities of anti-sRBC IgM antibody. When the complement and the secreted IgM coat sRBCs that surround the plasma cells, areas of hemolysis (plaques) appear against a lawn of sRBC that can be enumerated. At the center of each plaque is a single plasma cell

(AFC). Data are usually presented as IgM AFCs per million splenocytes. IgG AFCs can also be enumerated by slight modifications of this same assay. This isotype switching (from IgM to IgG) is important in secondary responses in which memory B cells respond more quickly to an antigen.

A second method to enumerate AFCs is by ELISPOT. This method is similar to the plaque assay described above with the exception that the splenocytes isolated from sRBC-sensitized mice are incubated on ELISPOT microtiter plates coated with either antimouse IgM or sRBC membranes to capture the secreted IgM. After incubation, the spleen cells are removed using a washing buffer followed by incubation with an enzyme-conjugated antimouse IgM antibody. A second washing step is used to remove unbound enzyme-conjugated antimouse IgM followed by addition of the chromogen substrate. The site at which each IgM secreting cell was present in the well of the ELISPOT microtiter plate is now visualized by the formation of a "spot" through the enzymatic conversion of the chromogenic substrate. Typically enumeration is performed using an ELISPOT reader that can rapidly quantify the number of spots (number of plasma cells) as well as the size and intensity (quantity of IgM being secreted) of the spots. It is noteworthy that in addition to enumeration of AFCs, the ELISPOT method can be applied to quantification of any secreted protein for which a suitable capture antibody exists. In evaluations of immunocompetent cells, the ELISPOT is especially useful for enumerating cytokine and chemokine secreting cells in which the desired endpoint is effector cell enumeration.

A third way the anti-sRBC humoral immune response can be evaluated is ex vivo using serum from peripheral blood of immunized mice and an enzyme-linked immunosorbent assay (ELISA) or other immunoassay methods. Although the optimal response is delayed by 1 to 2 days (compared to the AFC assay), this approach takes into account antigen-specific antibody secreted by B cells in the spleen as well as B cells residing in the bone marrow and lymph nodes. Peripheral blood is collected from mice (or other experimental animals) 6 days postimmunization with sRBCs. Serum from each sample is serially diluted and incubated in microtiter plates that have been coated with sRBC membranes or antimouse IgM, similar to that described above for the ELISPOT assay. After incubation of the test sera and a wash step, an enzyme-conjugated monoclonal antibody (the secondary antibody) against IgM (or IgG) is added. This antibody recognizes the IgM (or IgG) and binds specifically to that antibody. After incubation and a wash step, the chromogenic substrate is added. Conversion of the substrate by the enzyme conjugated to the secondary antibody results in a color change, which can be quantified by quantifying absorbance with a plate reader. Because this is a kinetic assay (color develops over time and is dependent upon the concentration of anti-sRBC antibody in the test sera), it is important to establish control concentration–response curves so that data can be evaluated in the linear range of the curve. In addition to evaluating serum, the supernatant from in vitro AFC assays can also be evaluated by ELISA. An advantage of the ELISA over the AFC assay and ELISPOT is the ability to attain a greater degree of flexibility, because serum or supernatant samples can be stored frozen for analysis at a later date. In contrast, a disadvantage of the ELISA approach is that it provides no information on the actual number of plasma cells that were induced by sRBC sensitization. Other T-cell-dependent antigens, including keyhole limpet hemocyanin (KLH) and vaccines (e.g., tetanus toxoid or hepatitis B surface antigen), are routinely used in multiple species including humans to drive an antigen-specific antibody response and to assess the potential for immunotoxicity (Plitnick and Herzyk, 2010). In larger species than mice, blood samples can be collected over multiple time points following immunization allowing for an assessment of the kinetics of the antibody responses, including different antibody isotypes.

B cell to plasma cell differentiation can also be monitored by flow cytometry. This can be accomplished utilizing intracellular staining for IgM (or other antibody isotypes such as IgG) to identify IgM^{high} cells in combination with the transmembrane proteoglycan, CD138, also termed syndecan-1, which is a hallmark of a fully differentiated plasma cell (Costes et al., 1999). It is noteworthy that even in resting B cells (i.e., not activated with antigen), background levels of intracellular IgM are readily detectable because the monomeric form of IgM serves as the BCR. For this reason, the designation IgM^{low} typically refers to a resting B cell versus IgM^{high}, which is indicative of high-level IgM expression as exhibited by plasma cells.

One final assay measures the ability of B cells to undergo blastogenesis and proliferation, which are critical steps in the generation of an antibody response. Lymphocyte proliferation is most often quantified either using a radioisotope-based assay or by flow cytometry. Splenocytes are stimulated in microtiter plates with a monoclonal antibody to surface Ig in the presence of IL-4, or with a B-cell mitogen such as LPS. Proliferation is evaluated 2 to 3 days after stimulation. In the radioisotope-based assay, proliferation is quantified by measuring incorporation of ^{3}H-thymidine into the DNA of the cultured cells. Data are usually expressed as mean counts per minute (cpm) for each treatment group. In the flow cytometry–based assay, cells are stained with one of several membrane permeable dyes such as carboxyfluorescein succinimidyl ester (CFSE). CFSE is a colorless dye that passively diffuses into the cell. Once inside the cell, CFSE undergoes cleavage by intracellular esterases to yield carboxyfluorescein succinimidyl, which is highly fluorescent and covalently reacts with intracellular amines. As the cell divides, the intensity of staining in each of the two newly formed daughter cells decreases by approximately half, as well as in every cell division thereafter. The number of cell divisions each cell has undergone is inversely proportional to fluorescence intensity. Alternatively cells can be treated with (5-ethynyl-2′-deoxyuridine [EDU]), which is a thymidine analog that incorporates into DNA during DNA synthesis. It can be subsequently detected using a click chemistry–based reaction that contains a fluorescent dye, which can also be detected by flow cytometry. For EDU, proliferation is directly proportional to fluorescence intensity. T-cell proliferative responses can be quantified using the same methodologies as described above with the exception that T-cell-specific stimuli are used to induce T-cell proliferation. Often in broad-based immunotoxicological evaluations, B-cell proliferative responses are measured in conjunction with T-cell proliferation.

Acquired Immunity: Cell-Mediated (CMI) While there are numerous assays used to assess CMI, three primary tests are used routinely in mice in the National Toxicology Program (NTP) test battery (see the section "The National Toxicology Program (NTP) Tier Approach"). The test battery includes the CTL assay, DTH response, and the T-cell proliferative responses to TCR stimulation (anti-CD3 plus IL-2), mitogens (phytohemagglutinin [PHA] and concanavalin-A [ConA]), and allogeneic cell antigens (mixed lymphocyte responses [MLR]). While these assays developed for mice use splenocytes, as described below, many of these assays have been adapted for larger species, including humans, using PBMCs.

The CTL assay measures the in vitro ability of splenic T cells to recognize allogeneic target cells (MHC mismatched) by

evaluating the ability of the CTLs to proliferate and then lyse the target cells. Splenocytes are incubated with P815 mastocytoma cells, which serve as target cells. The target cells are pretreated with mitomycin C or are irradiated so that they cannot proliferate. During this sensitization phase, the CTLs recognize the targets and undergo proliferation. Five days after sensitization, the CTLs are harvested and incubated in microtiter plates with radiolabeled (^{51}Cr) P815 mastocytoma cells. During this elicitation phase, the CTLs that have acquired memory recognize the foreign MHCI on the P815 cells and lyse the targets. At the end of the incubation, the culture plates are centrifuged, the supernatant is removed, and radioactivity released into the supernatant is quantified by a gamma counter. After correcting for spontaneous release, the percent cytotoxicity is calculated for each effector-to-target ratio and compared to that from control animals. Several flow cytometry–based methods that avoid the use of radionucleotides have also been developed to assay CTL activity the use of radionucleotides. One approach is similar to the approach described for the NK cell assay above, and involves the labeling of target cells with a fluorescent dye (e.g., DiO or CFSE) in order to discern target cells from effectors. After co-culture of target cells and CTL effectors, target cell viability is assessed by propidium iodide staining or using one of several other commercially available stains to assess viability. Another alternative nonradioactive surrogate assay widely used in place of measuring direct target cell killing is quantification of IFN-γ-expressing CD8$^+$ T cells by flow cytometry using intracellular staining. An inherent limitation to this last approach is that direct target cell killing is not assessed and it is assumed that all IFN-γ^+ CD8$^+$ cells identified are CTL effectors (see the section "Flow Cytometric Analysis"). Use of the CTL assay to evaluate the effects of xenobiotics on CMI function has been discussed by Burleson et al. (2010).

The DTH response evaluates the ability of memory T cells to recognize foreign antigen, proliferate, and migrate to the site of the infection, where they secrete cytokines and chemokines that promote the influx of other inflammatory cells. The assay quantifies the influx of mononuclear cells into the sensitization site. During xenobiotic exposure, mice are sensitized subcutaneously, between the shoulders, with two doses of KLH. On the last day of exposure, mononuclear cells are labeled in vivo with an IV injection of ^{125}I-5-iododeoxyuridine. One day later, mice are challenged intradermally in one ear with KLH. Twenty-four hours after challenge, animals are euthanized, the ears are biopsied, and radiolabeled cells are counted in a gamma counter. Data are expressed as a stimulation index, which represents the cpm of ^{125}I activity in the challenged ear divided by the cpm in the unchallenged ear. Alternative nonradioactive methods include systemic sensitization with sRBC, KLH or bovine serum albumin (BSA), followed by challenge (with the same antigen) in one footpad. Saline injection in the contralateral footpad serves as the control. Swelling into the challenged footpad as compared to the saline-injected footpad indicates activation of the DTH response (Dietert et al., 2009). It is important to note that alterations of DTH functional response may be influenced by disruption of either Th1-driven, antigen-dependent T-cell activation or mobilization of sensitized T cells to a local site (Dietert et al., 2010). DTH assays have also been developed for the NHP (Price, 2008; Bouchez et al., 2012).

T cells play a central role in CMI and their ability to undergo clonal expansion through proliferation is critical to this role. Several mechanisms exist to evaluate proliferative capacity. The MLR measures the ability of T cells to recognize foreign MHCI and MHCII on splenocytes from an MHC-incompatible mouse (allogeneic cells) and undergo proliferation. For example, splenocytes from B6C3F1 mice (responders) are incubated with splenocytes from mitomycin C–treated or irradiated DBA/2 mice (stimulators). Proliferation is evaluated 4 to 5 days after stimulation by quantifying uptake of ^{3}H-thymidine into the DNA of the cultured responder cells. Cells are collected from each well using a cell harvester and counted in a scintillation counter. Data may be expressed as either the mean cpm for each treatment group or as a stimulation index in which the index is calculated by dividing the cpm of wells containing responders and stimulators by the cpm of wells containing responders alone. Alternatively, cell proliferation can be quantified by flow cytometry using membrane permeable dyes such as CFSE or EDU (see the section "Flow Cytometric Analysis").

General T-cell proliferation can be evaluated in a manner similar to that described above for B cells (Table 12-5). Splenocytes or PBMC are stimulated in microtiter plates with monoclonal antibodies directed to the CD3 complex of the TCR (anti-CD3) and the CD28 T-cell co-receptor (anti-CD28), or with the T-cell mitogens Con A or PHA. Proliferation is evaluated 2 to 3 days after stimulation by quantifying uptake of ^{3}H-thymidine into the DNA of the cultured T cells or other nonradioactive methods. Data are usually expressed as mean cpm for each treatment group. As discussed above, proliferation can also be quantified by flow cytometry. These studies are usually done in conjunction with B-cell proliferative responses described above. In addition, T-cell activation can be measured by the upregulation of activation markers such as CD25 or CD69 as assessed by flow cytometry.

Flow Cytometric Analysis One of the most rapidly advancing areas and powerful tools in immunotoxicology has been the application of flow cytometry to investigations of immune modulation by xenobiotics. In the most general sense, flow cytometry is a method that employs light scatter, fluorescence, and absorbance measurements to analyze large numbers of cells (typically 5000 to 100,000 per sample) on an individual basis. Most commonly, fluorochrome-conjugated monoclonal antibodies raised against a specific protein of interest are employed for detection. The strength of the approach is that a wide variety of measurements can be made on large numbers of cells, individually, rapidly, and with a high level of precision. In addition, methods are also available that allow for the analysis of specific proteins in cell-free preparations such as cell lysates, biological fluids, and culture supernatants. A broad selection of polyclonal and monoclonal antibodies to cell surface markers, intracellular proteins, and secreted proteins are available (see Table 12-8).

The most common application of flow cytometry in immunotoxicology is to enumerate specific leukocyte populations and subpopulations. For example, antibodies are available to the T-cell surface proteins CD4, CD8, and CD3 (among others). Because flow cytometers can detect light emission of multiple wavelengths simultaneously, multiple-colored fluorochromes can be used concurrently facilitating an analysis of more than one protein simultaneously in a given sample (multicolor/parameter analysis). This approach can be used to provide insight into which specific T-cell subsets are targeted after exposure to a xenobiotic and to identify putative effects on T-cell maturation. Similarly, antibodies are readily available to identify other leukocyte subpopulations including antibodies to surface Ig, CD19, and B220 (the CD45 phosphatase on B cells) for enumerating B cells; Mac1 and F4/80 for macrophages; CD16/CD56 for NK cells in humans; and CD161 (NK1.1) for NK cells in mice. Surface marker analysis of heterogeneous cell preparations can reveal significant alterations in lymphoid subpopulations, and in many instances this is indicative of alterations in immunologic integrity. Indeed, an indicator of disease progression in AIDS can be monitored by changes in CD4$^+$ T-cell numbers. In their benchmark

paper, Luster et al. (1992) reported that in conjunction with two or three functional tests, the enumeration of lymphocyte subsets can greatly enhance the detection of immunotoxic chemicals. However, it is important to emphasize that although surface marker analysis can identify changes in leukocyte populations, functional analysis of the immune system is more definitive for the detection of immunotoxicity because the ability of immunocompetent cells to mount an effector response is assessed directly. Table 12-8 provides a list of common epitopes used to identify leukocyte populations in the mouse, rat, and human. In addition, flow cytometry is routinely used to purify and isolate leukocyte subpopulations from heterogeneous cellular preparations.

With the use of tetramers, flow cytometry can also identify antigen-specific T cells, especially those that recognize MHCI-restricted epitopes. Tetramers consist of four biotinylated MHC molecules connected by streptavidin. The MHC molecules include an antigenic peptide, usually of known sequence, that is known to activate an antigen-specific T cell. The tetramer is also conjugated to a fluorochrome that can be detected with a flow cytometer. Thus, tetramers will interact with its cognate T cell to allow for identification and quantification of antigen-specific T cells. One limitation with this technology is that the specific MHC (i.e., haplotype) must be known, as does the peptide sequence. An example is a tetramer to which the peptide SIINFEKL is bound, which specifically recognizes ovalbumin-specific $CD8^+$ T cells in mice with a $H\text{-}2K^b$ haplotype.

With technical advancements of flow cytometers (i.e., an increased number of wavelengths that can be simultaneously detected, enhanced sensitivity of detection, and more rapid analysis) coupled with a steady growth of applications, reagents, and methods, flow cytometry has become an integral tool in elucidating the cellular and molecular mechanisms of action produced by immunotoxicants. Current applications go well beyond strictly evaluating cell surface markers and include measurements of cellular viability, cell cycle, cell proliferation, intracellular free calcium, induction of apoptosis, DNA strand breaks (TUNEL assay), intracellular proteins (cytosolic and nuclear), membrane potential, intracellular pH, oxidative stress, and membrane lipophilicity (reviewed by Shapiro [2003], Hawley and Hawley [2004], and Bacher and Scheffold [2015]). Of particular utility in assessments of immune cell signaling and effector function has been the development of protocols and antibodies for intracellular staining of permeabilized cells. In the case of effector function, flow cytometry can be used to quantify the expression of multiple cytokines and/or chemokines simultaneously in individual cells by intracellular staining. Because activated leukocytes often secrete multiple regulatory factors simultaneously, termed "multifunctional," using intracellular staining in conjunction with extracellular staining for phenotypic markers to identify specific cell populations can provide important insights into the magnitude and profile of effects exerted by an immunotoxicant on specific cell types and populations. Measurements of regulatory factors in combination with phenotypic markers can be extended to also include markers of cell activation or differentiation to identify at which stage during effector cell generation an immunotoxicant is acting. For an example of intracellular cytokine staining see Karmaus et al. (2011). A second application of intracellular staining in flow cytometry has been for investigating cell signaling. The complex networks and pathways that control cellular activities can be studied on an individual cell basis to provide static or kinetic information in specific cell types. For example, by using intracellular staining, the abundance of specific signaling proteins, cytosolic and nuclear, can be quantified. In addition to signaling protein abundance, posttranslational modifications of proteins represent an important mechanism for transducing regulatory signals. One of the most extensively studied is protein phosphorylation and dephosphorylation, which often results in the activation or inactivation of protein function. The development of antibodies capable of distinguishing the point at which proteins possess phospho-groups at specific regulatory sites has made it possible to study modulation of distinct regulatory pathways by immunotoxicants. Because flow cytometers have the ability to detect 6 to 8 colors simultaneously, with more advanced instruments possessing 18 color capacity, it is possible to measure multiple signaling events and/or network interactions in single cells. This capability coupled with the fact that the flow cytometer can evaluate thousands of cells per second allows for accurate and reproducible detection of even rare events occurring in small subsets of leukocytes. Moreover, flow cytometry has numerous advantages over other approaches such as Western blotting and immunoprecipitation because of the rapidity of analysis and in not being a bulk lysis method in which all cells in a given sample are pooled for analysis to render results that are representative of the overall mean within the entire cell population rather than in individual cells. For examples of applying the measurement of intracellular phosphoproteins and transcription factors by flow cytometry to studying mechanisms of immune modulation see North et al. (2010) and Lu et al. (2011).

Another major advancement in flow cytometry–based analyses has been the development of fluorescent microspheres that are individually identified by the instrument. By coating the surface of microspheres with various concentrations of two fluorescent dyes, sets of microspheres can be generated with each set possessing a unique spectral signature. Subsequently, various materials (i.e., proteins, antibodies, or nucleic acids) can be covalently conjugated to the surface of these microspheres in order to create unique detection systems. This technology is being widely applied for analyzing a broad variety of soluble cellular components including proteins in cell free preparations by flow cytometry. For example, up to 15 different cytokines can be quantified simultaneously in

Table 12-8

Phenotypic Markers to Identify Immune Cells

IMMUNE CELL TYPE	HUMAN	MOUSE	RAT
B Cell	CD19	CD19	Surface IgM Surface IgG
T Cell	CD3	CD3	CD3
T-helper Cell	CD4	CD4	CD4
Cytotoxic T lymphocyte	CD8	CD8	CD8
γδT Cell	γδTCR	γδTCR	γδTCR
NK Cell	CD16 CD56	NK1.1	CD161
Monocyte	CD14	CD11b	CD11b/c
Macrophage	CD11b	F4/80	CD11b
Dendritic cell	CD1c CD83 MHCII	CD11c MHCII	CD11b/c CD103 MHCII
Plasmacytoid dendritic cell	CD303		

cell supernatants or biological fluids (e.g., brochoalveolar lavage fluid, BALF). A major advantage of this method over more traditional approaches, such as ELISA-based assays, is that only small amounts of biological samples and reagents are required because multiple proteins are assayed simultaneously. The same technology is also being applied for analyzing cell lysates for changes in protein phosphorylation in investigations of cell signaling.

A recent flow cytometry advancement is the ability to quantify gene-specific mRNA levels in individual cells using a technique termed PrimeFlow®. The methodology is based on the principle of using antisense probes containing 20 to 40 oligonucleotides that hybridize to target mRNA. Using branched-DNA technology, the signal is amplified by binding of preamplifiers then amplifiers and finally the fluorochrome-conjugated probes, thus allowing for sufficient amplification to facilitate accurate quantification of gene-specific mRNA transcripts. The current technology will accommodate detection of two different mRNA species simultaneously. Quantification of modestly expressed mRNA species is presently a limitation of this technique. PrimeFlow® has a wide array of applications in immunotoxicology including identifying cell types that are the source of regulatory proteins (e.g., cytokine and chemokines), as these are typically made on demand and regulated at the transcriptional level.

Flow cytometry has become a powerful tool for characterizing the cellular and molecular mechanisms associated with immunotoxicants. For information concerning specific flow cytometry protocols and applications beyond those provided by commercial vendors, the reader is directed to several references including *Practical Flow Cytometry in Haematology: 100 Worked Examples* by Leach et al. (2015), the 3rd edition of *Methods in Molecular Biology: Flow Cytometry Protocols* by Hawley and Hawley (2016), and the Purdue University Cytometry Laboratories Web site www.cyto.purdue.edu/, which hosts a blog to which one can submit questions to the broader community of flow cytometry users for technical assistance.

Measurements of Cytokines and Cytokine Profiling As discussed in the earlier part of this chapter, development, maturation, differentiation, and effector responses of the immune system are highly dependent on a multitude of small, secreted proteins termed cytokines. In most cases, these immunological processes are controlled by the production of multiple cytokines, some of which are released simultaneously, whereas others are released in a very defined temporal sequence. Many of these cytokines are produced by T cells and are the mechanism by which a wide variety of functions by T cells are mediated. Due to the importance of cytokines in regulating the immune system, xenobiotics that alter the production and release of these mediators can significantly affect immune competence. Therefore, quantification of multiple cytokines, often referred to as cytokine profiling, has become routine in immunotoxicology and can provide significant insights into the mechanisms by which a xenobiotic produces its immunotoxicity. For example, cytokine profiling has been explored as an approach for identifying chemical allergens, either contact sensitizers, which typically induce a Th1 profile of cytokines (IL-2, IFN-γ, and TNF-β), or respiratory sensitizers, which typically produce a strong Th2 cytokine profile (IL-4, IL-5, IL-6, and IL-10) (Mosmann and Coffman, 1989; Mosmann et al., 1991). Cytokines can be quantified in cell culture supernatants or biological fluids (i.e., serum or BALF) by ELISA or by multiplex assays. Quantification of test samples is accomplished by comparison to a standard curve employing recombinant cytokine standards. The aforementioned ELISPOT assay can also be used to quantify the number of cells producing the cytokine of interest. Likewise flow cytometry can be used to identify cytokine-producing cells by intracellular staining or to quantify cytokines in media or biological fluids, with the main advantage being that the source of the cytokine(s) can be identified using the former approach, and that many cytokines can be assayed simultaneously from one sample using the latter approach (see the section "Flow Cytometric Analysis"). Because cytokines are regulated transcriptionally and then actively synthesized by cells at the time they are secreted, rather than existing as stored proteins, measurements of cytokine mRNA levels has become another common approach of assessing which cytokines are being expressed at a given time, and the putative effects xenobiotics exert on their regulation and expression. Real-time polymerase chain reaction (PCR) is most commonly used for quantifying mRNA levels of specific cytokines as well as for other genes of interest in cells or tissues but other approaches, such as RNAseq, are used for more global assessments. Major advantages to quantifying cytokine expression at the mRNA rather than protein level include significantly greater sensitivity, the ability to quantify expression in solid tissues, and the capability to rapidly design appropriate reagents (PCR primers) specific for any cytokine. A major disadvantage is that changes at the mRNA level for a given cytokine may not necessarily correlate with changes in protein. Another disadvantage compared to flow cytometric determinations by intracellular staining is not knowing the cell type(s) from which the cytokines are being produced. One additional limitation to cytokine measurements by ELISA or via quantification of cytokine mRNA levels is that neither of these approaches provides information concerning the biological activity of the proteins being measured. Additionally, as described by Corsini and House (2010), multicytokine analysis still needs to be standardized in terms of optimum sources for analysis, protocols, and quality control issues, such as the use of reference standards and the expression of results.

Cytokine Release Assays Therapeutic monoclonal antibodies and pleiotropic cytokines have the potential to lead to the activation of a number of immune cells (primarily T cells and monocytes/macrophages) by the initiation of a cascade that causes the release of cytokines, including TNF-α, IFN-γ, and IL-6. Cytokine release syndrome (also known as cytokine storm) can be characterized by flu-like symptoms, fever, chills, headache, back pain, hypotension, and organ failure. Cytokine release is, at least in part, responsible for several drug-induced immune-mediated adverse reactions described in the literature including first-dose reactions, infusion reactions, tumor-lysis syndrome, and systemic inflammatory response syndrome and, under physiological conditions, can contribute to the pathology following infection with certain pathogens (Gribble et al., 2007). In 2005, an anti-CD28 super costimulatory agonist (TGN1412 monoclonal antibody), which bypasses the need for antigen signaling and leads to polyclonal T-cell expansion, was administered to six healthy male volunteers in a first-in-human trial and within 90 minutes of the first dose there was a profound impact on the immune system that resulted in an acute cytokine release, systemic inflammatory response, and ultimately multiorgan failure (Suntharalingam et al., 2006). This response was not predicted by in vitro human cell–based assays or from toxicology studies conducted in NHPs, highlighting the limitations of these approaches to always predict adverse effects. The mechanisms responsible for cytokine release by monoclonal antibodies can include the cross-linking and clustering of antigen targets on the immune cells by the Fab arms, by interaction of the Fc region of the monoclonal antibodies with Fc gamma receptors on NK cells, monocytes, and/or neutrophils, or by ADCC. To evaluate for the potential to induce

cytokine release in humans, monoclonal antibodies are often evaluated using an in vitro cytokine release assay with human cells. An overview of current practices for conducting cytokine release assays was published (Finco et al., 2014). Methods include whole blood or PBMCs and presentation of monoclonal antibodies either in solution, immobilized by coating onto assay plates, or via capture with anti-Fc antibodies coated to assay plates. Briefly, the biotherapeutic is incubated with cells from multiple human donors for up to 72 hours and the supernatant evaluated for a panel of cytokines with the response being compared to the appropriate positive and negative controls. The specific method utilized should be scientifically justified based on the pharmacology of the drug.

Host Resistance Assays Host resistance assays represent a way of assessing how xenobiotic exposure affects the ability of the host to combat infection by a variety of pathogens. Although host resistance studies provide significant insight into the mechanisms by which an immunotoxicant is acting, these assays are not used as a first or only choice for evaluating immune competence. The results from host resistance assays are typically more variable than other immune function assays already discussed and therefore require markedly greater numbers of animals in order to obtain statistical power. The increased number of animals required coupled with challenging animals with a live pathogen also raises ethical considerations as well as cost. In addition, as with other immune function tests, no single host resistance model can predict overall immune competence of the host, primarily because each model uses different mechanisms for elimination of various pathogens. A representative list of host resistance models is shown in Table 12-9. Typically, three challenge levels of pathogen (approximating the LD_{20}, LD_{50}, and LD_{80}) for each concentration of xenobiotic are used in order to be able to detect both increases and decreases in resistance. Endpoint analyses are lethality (for bacterial and viral pathogens), changes in tumor burden, and increased or decreased parasitemia. In host resistance studies, it is also important to consider the following: (1) strain, route of administration, and challenge levels of the pathogen; (2) strain, age, and sex of the host; (3) physiologic state of the host and the pathogen; and (4) time of challenge with the pathogen (prior to, during, or after xenobiotic exposure). All of these can have significant effects on the results from any individual study.

A major advantage in applying host resistance models to investigations of immunotoxicity is the ability to study the effects of an immunotoxicant within the context of the intact immune system encompassing all its diversity as it acts to protect the host against a bona fide pathogen. It is important to emphasize that the immune system possesses significant redundancy (i.e., multiple mechanisms to provide defense against invading microorganisms). Therefore, even if a particular cell type or effector response has been compromised by exposure to an immunotoxicant, other components of the immune system might provide partial or complete protection to the host from pathogen challenge. In addition, certain pathogens are restricted to specific tissues or anatomical sites, for example, influenza virus, which is typically restricted to airways. Using host resistance models permits the study of immunotoxicants and their effects within the environment and in the context of the tissue targeted by the pathogen (Buchweitz et al., 2007). A variety of host resistance models have been reviewed including bacterial challenge models (Burleson and Burleson, 2010), viral host resistance models (Freebern, 2010), parasite challenge models (Luebke, 2010), and tumor challenge models (Ng et al., 2010).

Assessment of Developmental Immunotoxicology (DIT) Interest in DIT is predicated on the recognition that the developing immune system represents a novel target for xenobiotic-induced toxicity that presents some special considerations when it comes to assessment. The concept that any of a number of dynamic changes associated with the developing immune system might provide periods of unique susceptibility to chemical perturbation has been reviewed (Dietert et al., 2000; Holladay and Smialowicz, 2000). This unique susceptibility may be manifested as a (1) qualitative difference, in the sense that a chemical could affect the developing immune system without affecting the adult immune system; (2) quantitative difference, in the sense that a chemical could affect the developing immune system at lower doses than the adult immune system; or (3) temporal difference, in the sense that a chemical could produce either a more persistent effect in younger animals than adults, or trigger a delayed effect (i.e., the consequences of early exposure are not manifested until early adulthood). As a result, while effective assessment of DIT should certainly draw upon the prior experience gained from adult-exposure immunotoxicity assessments, it is important to examine the database of known immune changes that reflect the potential for unique susceptibility and are specific for the developing immune system (Dietert and Piepenbrink, 2006b). It is also noteworthy that development of leukocyte progenitors from bone marrow stem cells ultimately giving rise to mature immunocompetent cells is a life-long cell renewal process not unique to early life stages.

One of the most comprehensive reports to date attempted to compare the immunotoxicity following developmental or adult exposure to the following compounds: diethylstilbestrol, diazepam, lead, 2, 3, 7, 8-tetrachlorodibenzo-*p*-dioxin (TCDD), and tributyltin oxide (Luebke et al., 2006a). The selection of these five compounds was reported to be based on the availability of some human data. The authors concluded that for all five chemicals, the developing immune system was found to be at greater risk than the adult, either because lower doses produced immunotoxicity, adverse effects were persistent, or both. However, it is noteworthy that no developmental immunotoxicants have been identified that have not also been immunomodulatory in the adult animal. Importantly, this observation may merely reflect the state-of-the-science; that is, all published DIT studies to-date have been conducted on known adult immunotoxicants, and systematic studies comparing the effects across multiple developmental windows are still uncommon.

A better understanding of the developing immune system, particularly, an understanding of critical developmental hallmarks, has prompted some to speculate about the existence of five critical windows of vulnerability as outlined in Fig. 12-21 (Dietert et al., 2000). The first window encompasses a period of hematopoietic stem cell

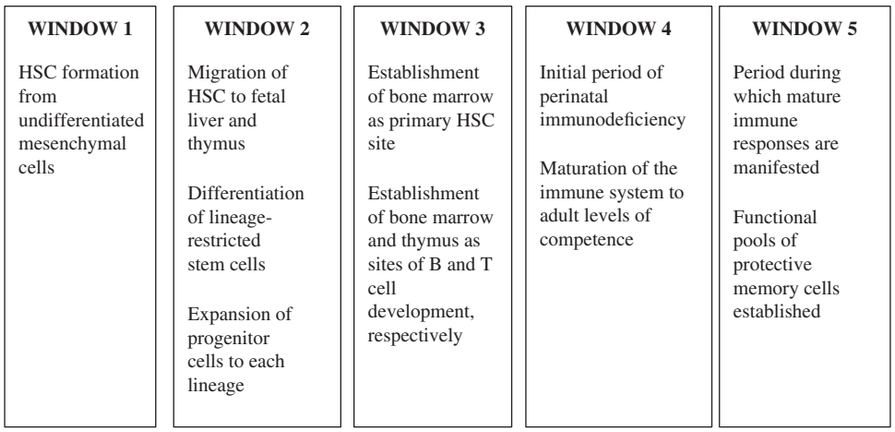

Figure 12-21. *DIT windows of sensitivity.* Five developmental windows of sensitivity to immunotoxicity have been identified.

formation from undifferentiated mesenchymal cells. Exposure of the embryo to toxic chemicals during this period could result in failures of stem cell formation, abnormalities in production of all hematopoietic lineages, and altered immunocompetence. The second window is characterized by migration of hematopoietic cells to the fetal liver and thymus, differentiation of lineage-restricted stem cells, and expansion of progenitor cells for each leukocyte lineage. This developmental window is likely to be particularly sensitive to agents that interrupt cell migration, adhesion, and proliferation. The critical developmental events during the third window are the establishment of bone marrow as the primary hematopoietic site and the establishment of the bone marrow and the thymus as the primary lymphopoietic sites for B cells and T cells, respectively. The fourth window addresses the critical periods of immune system functional development, including the initial period of perinatal immunodeficiency, and the maturation of the immune system to adult levels of competence. The final window addresses the subsequent period during which mature immune responses are manifest, and functional pools of protective memory cells are established.

Most recently, considerable attention has been focused on the perinatal period (i.e., prior to and just after birth) because this window of development is known to be replete with dynamic immune changes, many of which do not occur in adults (Dietert and Piepenbrink, 2006b). Indeed, one reality associated with DIT windows is that the developing immune system exists in an unbalanced state through the latter portion of gestation with certain functional CMI capacities deliberately impaired. In fact, Taylor et al. (2006) demonstrated that placentally induced immune skewing via the release of Fas-ligand-containing exosomes is one hallmark of a successful pregnancy brought to full term. Upon birth, restoring effective immune balance through the enhancement of Th1 capacity in the newborn is critical for protecting childhood health (Holt et al., 2005; Yun and Lee, 2005). Prenatal maturation and functional skewing of the fetal immune system followed by the rapid reversal of the imbalance at birth have features that are not effectively modeled using adult exposure-assessment (Dietert and Piepenbrink, 2006b), and DIT is best viewed as a continuum of alterations. Suppression of the developing immune system, manifested as increased susceptibility to infections and cancer, is not the only concern. Immunotoxic changes that increase the risk for allergic or autoimmune responses in later life should also be considered (Edwards and Cooper, 2006; Selgrade et al., 2006; Yeatts et al., 2006). Adding to the complexity is the demonstration that some developmental immunotoxicants seem capable of inducing targeted immune suppression, while at the same time elevating the risk of allergy and/or autoimmunity (Haggqvist et al., 2005). Because either significant immune suppression or disrupted immune regulation is a concern and needs to be detected, the most effective methodology for assessing DIT must also be capable of assessing significant changes in immune balance.

In spite of the increased interest in assessing the potential for developmental immunotoxicity, it must be emphasized that neither validated nor widely accepted methods currently exist for evaluating the effects of a chemical on the developing immune system. Several workshops have summarized consensus thinking concerning DIT evaluation (Dietert et al., 2000; Holsapple, 2002b; Luster et al., 2003; Van Loveren and Piersma, 2004; Holsapple et al., 2005; Ladics et al., 2005) and a number of reviews have been written (Holsapple et al., 2003, 2004, 2007; Luebke et al., 2006a; Dietert and Piepenbrink, 2006b; Dietert and Holsapple, 2007; Burns-Naas et al., 2008; Dietert and Burns-Naas, 2008; Weinstock et al., 2010; Winans et al., 2011). Additionally, other reviews have dealt with issues concerning immunotoxicity evaluation across various life stages (Germolec et al., 2004; Holsapple et al., 2005; Ladics et al., 2005; Ravel and Descotes, 2005). Below is a brief discussion of critical issues requiring consideration in establishing a testing framework.

In constructing a DIT testing framework, one of the first points to consider is the selection of an animal model. Consistently, the rat has been identified as the preferred species for evaluations of DIT, largely due to the fact that the rat has been utilized extensively in guideline developmental and reproductive toxicology testing. However, the NHP is often employed for many biopharmaceuticals where the NHP is the only relevant pharmacologic species. A review of the anatomical and functional differences in the immune systems of the mouse, rat, dog, primate, and human, and their use as models for DIT testing concluded that the developing immune systems of mice and humans have been best characterized to date, and immune ontogeny in the mouse and rat is likely similar (Holsapple et al., 2003). Another important consideration when selecting a species is that the development of the immune system in the rodent is delayed relative to the human, and how this differential maturation will impact data extrapolation for predicting human risk. For example, some developmental landmarks observed in utero in humans occur after parturition in the rat.

A second consideration when constructing a framework for assessing DIT concerns sex-specific effects. Results from perinatal exposure to xenobiotics suggest that significant sex-based differences in immunotoxic sensitivity are common and are at least

as prevalent, if not more frequent, compared with the incidence observed following adult exposure-assessment (Luebke et al., 2006a; Dietert and Piepenbrink, 2006b). As such, for the evaluation of DIT, testing of both sexes may be critical.

A third major consideration in a DIT testing framework is consideration of exposure. There is general agreement that the best exposure protocol is one where exposure occurs across all nonadult developmental windows followed either by immediate assessment or assessment after a few weeks (Luster et al., 2003; Holsapple et al., 2005; Ladics et al., 2005). Exposure to pregnant dams has been a hallmark feature of most DIT protocols, and the maternal influences on exposure to the fetus/newborn pups would be dependent on transfer of the xenobiotic either across the placenta or via lactation. The gestational (e.g., transplacental) and lactational periods in the rat would result in exposure from conception to early postweaning in the pup, approximately 3 weeks of age. Direct exposure of pups via the diet would generally commence at about 3 weeks after birth. An unresolved issue is whether direct exposure of the pups, which is generally accepted as a routine procedure at around postnatal day 7, should occur during the lactational period as well (Ladics et al., 2005); however, any decisions concerning this issue will require consideration of how humans would be exposed and the specific properties of the chemical being studied. For example, if exposure is only oral and there is no reason to believe that the lactational transfer differs significantly for a class of compounds between rat and human, then direct dosing of pups could be initiated postweaning. In addition, information on pharmacokinetic and dosimetry could be useful in determining whether any direct dosing of pups during lactation is necessary. However, it is important to emphasize that this type of information is not routinely available for most xenobiotics.

A fourth consideration in creating a DIT testing framework concerns which specific endpoints to measure. Immune organs, such as the thymus, spleen, lymph nodes, and/or bone marrow, are not typically assessed in routine developmental and reproductive toxicology studies. However, it has been the consensus of a number of workshops that histopathological evaluation of these immune organs could be easily integrated into existing protocols and is occurring for pharmaceuticals when there is a cause for concern (Luster et al., 2003; Holsapple et al., 2005). There is still uncertainty whether routine histopathology is sufficiently sensitive to detect all potential immunotoxic effects, especially when the unique characteristics of the developing immune system, as discussed above, are considered. Indeed, there are examples where morphometric histopathologic findings do not predict functional impairments due to toxicity produced on the developing immune system (Hussain et al., 2005). Ultimately, while the use of specific, rather than general, histopathology has been recommended, it has been also suggested that functional tests be employed in the assessment of DIT. Unfortunately, few if any functional assays have been validated for detection of DIT, even for routine assays such as the TDAR, which has largely been confined to adult exposure protocols. Results published on several chemicals and drugs in recent years suggest that functional tests are a frontline priority for perinatal immunotoxicity detection and that a combination of at least two functional tests, such as a multi-isotype TDAR, and a CMI response assay, such as the DTH assay and/or CTL or NK cytotoxicity assay, should be paired with histopathological analysis and phenotypic analysis of lymphocyte subsets using flow cytometry (Dietert and Piepenbrink, 2006b).

One final point regarding DIT needs to be considered. As developmental immunotoxicity protocols are inserted into existing toxicology testing regimes, such as developmental and reproductive toxicology protocols, immunization protocols are often incorporated. This approach has raised concerns among those evaluating other physiological systems (e.g., reproductive and neurological) in terms of potential immunization-induced changes. However, investigations addressing this potential by determining the impact of the incorporation of immunotoxicological functional assays on standard toxicological studies in rats have been largely negative. Ladics et al. (1995) showed that immunization did not significantly alter the weights or morphology of routine protocol tissues with the exception of the spleen (i.e., which manifested the anticipated increases in the numbers and size of germinal centers). In a subsequent study by this same group, immunization did not alter any hematological or clinical chemistry parameters, or lymphocyte subset numbers (i.e., measured on peripheral blood with a flow cytometer), and did not mask the anticipated hepatotoxic effects of subchronic exposure to carbon tetrachloride (Ladics et al., 1998). An additional component of this discussion is the reality that the species being modeled, the human, has immunizations as a routine lifelong component of preventative medicine. As such, to avoid all immunizations in animal evaluation protocols does not closely simulate the childhood experience. Additionally, until the immune system is asked to respond specifically to a foreign antigen, the capacity to detect immunotoxicity may be severely limited. Therefore, immunization and a range of functional T-cell-dependent immune response evaluations seem necessary as components of an effective DIT assessment.

Assessment of Hypersensitivity Responses As emphasized throughout this chapter, immunotoxicology has evolved to the point where an ever-increasing number of studies are being conducted to characterize the immunotoxicity of a variety of xenobiotics using standard immunotoxicological parameters. Depending on the specific drug/chemical, the exposure conditions, the species being tested, and the immune parameter being measured, the outcomes can be manifested as decreases, increases, or no effect. While there is no question that the most frequent observation has been immune suppression, there is also no doubt that some examples of immune stimulation have been reported, a profile consistent with the concept of immunotoxicology existing as a continuum (Fig. 12-1). However, this observation can trigger some important questions. Should a treatment-related increase in an immune parameter such as the TDAR be considered an adverse response? Should an increase in the antibody response to a neoantigen be considered a harbinger of autoimmune potential? There simply is no consensus regarding the correct way to interpret an increase in immune parameters such as the TDAR, which were primarily developed to characterize the immunosuppressive potential of xenobiotics. The adverse consequences of exaggerated immune function do reflect an inability to recognize self, and are generally depicted as hypersensitivity and autoimmunity.

Drugs and chemicals that are capable of eliciting an immune response are generally low-molecular-weight substances possessing some inherent reactivity. There is a genetic susceptibility to hypersensitivity responses in that not all individuals react to the same drugs and chemicals. For the most part, the xenobiotic cannot be considered an antigen, simply because by itself it is not capable of stimulating an immune response. Instead, the xenobiotic becomes a hapten, which triggers the immune response in some tissue in the host. This property is called the sensitizing potential of the hapten and is associated with its inherent reactivity. Hapten-specific immune responses are therefore triggered only in the presence of the hapten–carrier complex and can be mediated either by humoral immunity or CMI. The damage associated with any type of hypersensitivity response can be directed against the tissue that

is bound by the hapten. One of the most important and challenging problems in the field of immunotoxicology is determining the potential for chemicals to induce immune modulation and, in the current context, to demonstrate the sensitizing potential of xenobiotics. Thus, it becomes essential to have validated predictive animal models, and to understand the underlying mechanisms of action. The following is a discussion of the currently used methods of predicting the most frequently occurring hypersensitivity reactions to chemicals, Type I and Type IV, which are most often manifested as respiratory hypersensitivity and contact sensitization, respectively.

Assessment of Respiratory Hypersensitivity in Experimental Animals Methods for assessing the potential to induce respiratory hypersensitivity have been reviewed (Holsapple et al., 2006). The objectives of this review were to describe the appropriate methods for identifying and characterizing respiratory hazards and risks and to identify the key data gaps and related research needs. The review addressed these objectives from the perspectives of proteins, chemicals, and drugs, and emphasized the important roles played by IgE and Th2 cell–mediated responses, while recognizing that damage to the respiratory tract can be triggered either by nonspecific irritation or by other specific immune-mediated mechanisms (i.e., not IgE- or Th2-mediated).

Animal models for respiratory hypersensitivity has been reviewed (Pauluhn, 2005). Current assays utilize two phases: induction/sensitization and challenge/elicitation. The induction phase usually includes multiple exposures to the test compound (sensitization) via the respiratory tract (i.e., inhalation and intranasal or intratracheal instillation) or by dermal contact. There are advantages and disadvantages to each. Inhalation more closely represents environmental exposure by allowing for chemical contact with the upper as well as the lower respiratory tract. However, the equipment required is expensive and difficult to maintain. Exposure via the intranasal route is easily accomplished and allows for distribution of antigen to the upper and lower respiratory tract; however, studies have shown that a large proportion of the material can be recovered from the stomach (Robinson et al., 1996). In contrast, intratracheal instillation results in exposure to the lower respiratory tract only. The observation that a predominant respiratory sensitizer would still trigger an IgE response when applied topically has suggested an important interplay between Type I and Type IV hypersensitivity reactions. The basis for this observation can be accounted for by a cytokine network model, which involves important cross-talk between humoral immunity and CMI. Basically, a chemical with the capability of being a respiratory sensitizer will trigger an IgE response regardless of its route of exposure because it "selects" or supports the development of a Th2-dependent response, with the associated cytokine profile: IL-4, IL-5, IL-10, and IL-13. In contrast, a chemical that lacks the capability of being a respiratory sensitizer but can still trigger contact dermatitis will select or support a Th1-dependent response, with the associated cytokine profile including IL-2 and IFN-γ.

The challenge (elicitation) phase involves exposure to the chemical (hapten), the homologous protein conjugate of the hapten, or the antigen. Endpoints to characterize a positive response range from the induction of Igs (i.e., total IgE for chemicals or specific IgE for protein antigens), cytokines, or lymphokines in serum, to pathophysiological responses, including the influx of inflammatory cells and the onset of bronchoconstriction along with the associated changes in respiratory functional parameters. The latter may be accomplished by visual inspection of the animals' respiratory pattern or more quantitatively by plethysmography. With plethysmography, changes in the respiratory rate, tidal volume, and plethysmographic pressure can be measured. However, plethysmography in guinea pigs, rats, and mice can be technically challenging and labor intensive. In addition, there is some controversy over the interpretation of measurements made from whole body plethysmography, and whether these measurements truly reflect changes in airway mechanics (Lundblad et al., 2002; Mitzner and Tankersley, 2003).

None of the currently applied animal models duplicate all features of human asthma, and most of the current animal models were developed for studying specific hypersensitivity responses to high-molecular-weight protein allergens (Pauluhn, 2005). Fewer animal models have been developed for use in the area of chemically induced respiratory allergy, which is a key data gap (Holsapple et al., 2006). One of the limitations associated with low-molecular-weight models is that often these compounds must conjugate with host proteins to become antigenic (i.e., form hapten–carrier complexes). Often, a challenge with the conjugated chemical is necessary to induce a pulmonary response. Adding this variable can make the analysis of test results more difficult. False-negative results may occur due to variability in test article conjugation, and chemical conjugates are also necessary to measure specific immunologic responses.

The majority of the current animal models are based on antibody-mediated events occurring as a reflection of the induction phase (Pauluhn, 2005). In certain cases, immunologic sensitization may be confirmed by the detection of antigen-specific antibody; however, subsequent challenge does not produce clinical signs of respiratory distress. It is also possible to detect pulmonary sensitization in animal models where there is no detectable antigen-specific antibody production. In these cases, CMI or other mechanisms may be involved, or there may be difficulty in antibody detection.
